Major Sharpe (Colorado) says, "Observation made during the past year, both in the Tropics and at the various posts in this Department, strongly confirms the opinion expressed by me in former reports that the legislature of last winter abolishing the canteen was ill advised. If there is no authorized and decently kept place of resort within a garrison where the soldier can find recreation suited to his tastes and station in life, he will seek it outside, and the innumerable brothels and whisky dens which are springing up on the edge of the reservations will prove the most baleful and destructive enemy to contentment and good order with which a garrison can be cursed."

Major George M. Dunn, Judge-Advocate, Department of Cuba, in discussing the abolition of the Canteen, says, "During November, December, and January, 1900, with the Canteen, there were 139 convictions for drunkenness, and during the months of March, April, and May, 1901, the Canteen having been abolished, there were 275 convictions for drunkenness, or nearly twice as many, due to the abolition of the Canteen."

I have given these reports, letters, resolutions, and discussions in order that a correct and impartial verdict may be reached and I have endeavored to be as moderate as possible.

After patient effort covering a few months I have accumulated a mass of evidence in favor of the Canteen which, were it all published, would constitute a volume of itself, but I have tried to give that which practically expresses the sentiments of all.

I have talked with men and women of integrity and knowledge in my native town, workers in the Y. M. C. A., Sabbath school teachers, and have by every available means sought to get the expressions of the most conservative.

While we can readily appreciate that others may sincerely differ in their opinion from us yet the fact remains that the medical and military officers of the Army are without doubt in a position to judge most clearly of the benefits and evils of the Canteen.

I have been surprised in this connection at the ignorance of several intelligent persons of my acquaintance regarding the name "Canteen," they having been, heretofore, under the impression that the canteen was a liquor flask issued by the Government and worn by the soldier in camp and out of it. I am free to confess that for some time I was under the same false impression. These remarks are made only that we may in some slight manner appreciate the ignorance of the general public on such questions and how blindly it follows the leader without "rhyme or reason."

In closing I wish to thank the many Senators, Congressmen, and Government officials, and many others, who have rendered me great assistance in a most prompt, courteous and obliging manner.

THE ROENTGEN METHOD IN THE DIAGNOSIS OF RENAL AND URETERAL CALCULI.[1]

BY CHARLES LESTER LEONARD, A.M., M.D.,
OF PHILADELPHIA.

THROUGH the adaptation of the discoveries of pure science, the art of medicine and surgery is becoming an applied science. The discovery that has probably exerted the greatest influence is that of the lens and its adaptation in the microscope. Roentgen's discovery is almost as fundamental. We cannot see into the future or estimate whether its influence will be as widespread. It already forms the basis for a new and valuable method of diagnosis and has also given rise to a new therapeusis. Whether the Roentgen rays are the therapeutic agent, or, as it will probably be proved, only another method of employing electricity, the discovery by Roentgen is responsible for its introduction.

The application of this method of diagnosis is gradually extending, as the technic essential to its employment in various fields of diagnosis is developed. In many cases it has become the most accurate method of diagnosis, and its accuracy has often shown the errors and defects of older methods. It cannot, however, be insisted upon too frequently that it is essentially a method of diagnosis, and that, as such, it should be used by professional men only. The diagnostician must possess professional knowledge, special technic and clinical experience with this method.

The advance made in the diagnosis of calculous conditions of the kidneys and ureters by the employment of this method illustrates its pos-

[1] Read before the Society of Alumni of Bellevue Hospital, Nov. 8, 1901.

sibilities in other fields, and the effect which it has had upon the methods of operating and treatment in these cases demonstrates its value.

In suspected renal lithiasis, when the typical symptoms are wanting or confused, a differentiation from diseases of neighboring organs is often impossible by the older methods. On the other hand, a calculus may be present and yet the absence of certain symptoms may produce a symptom-complex that points to disease of a neighboring organ. Thus, in one case in which the diagnosis lay between ureteral calculus, chronic ovarian disease and appendicitis, the Roentgen examination excluded calculus and the operation freed a chronically inflamed ovary bound down by dense adhesions. In another case that had baffled a number of clinicians by the indefiniteness of the other symptoms and the persistent character of the pain, the skiagraph showed six phleboliths which the operation proved were in a varicocele of the broad ligament. On the other hand, in a case that had been diagnosed "nervous dyspepsia," the colic and gastric crises were found to have been caused by a calculus impacted in the ureter; its position also explained the absence of pathological elements in the urine at the time of the attacks, as it produced a unilateral anuria.

The differentiation between renal lithiasis and other forms of nephritic disease is often even more difficult. A small calculus in the kidney may give rise to symptoms identical with those of incipient, malignant or tuberculous disease. The unrecognized presence of a small calculus in the calyces or pelvis of the kidney or in the ureter is, however, a menace to its integrity and functional activity. These small calculi often block the ureter and cause anuria and the destruction of the kidney. The Roentgen method of diagnosis has shown that these calculi in their passage through the ureter give rise to "renal colic" more frequently than do calculi in the calyces or pelvis of the kidney. More than sixty per cent. of the calculi detected by the author have been found in some portion of the ureter.

The recognition of this larger portion of ureteral calculi points, however, to the facility with which they can pass through the urinary tract without, in the majority of cases, producing severe symptoms. Undoubtedly many more are passed than are brought to the attention of the surgeon. In the inability to recognize and locate the seat of obstruction lies the gravest source of danger. Now, that these calculi can be found and their size and position determined, the gravity of the situation is decreased; conservative surgery[1] can rationally wait for Nature to expel them, or, if necessary, immediate operation can be directed to the exact seat of the lesion.

The value of this method is easily realized in cases of complete obstructive anuria. The recognition of the calculus as the obstruction directs operation to it and prevents operation upon the wrong kidney. In unilateral anuria, when an unrecognized calculus completely obstructs the ureter, all urgent symptoms subside and the patient believes that the trouble is over. Unless a calculus is passed and recognized, the subsidence of symptoms should be construed as an indication of grave danger. The integrity and functional life of the kidney are threatened. If the patient has not been examined by the Roentgen method, it should be done immediately. If a calculus is found and a cystoscopic examination shows the absence of urinary flow from the affected side, immediate operation is indicated. If, however, urine is passing, and the skiagraph shows the calculus to be of a size that can be expelled, the operation can be postponed. Post-mortem examinations have shown how frequently the destruction of a kidney takes place after calculous anuria has terminated its functional activity.

Temporary unilateral anuria can be produced by calculus impaction, twists of the ureter, valvular formations and shifting or movable kidneys. The similarity in symptomatology is often such that the passage of the ureteral calculus cannot be differentiated from the other conditions, except by the Roentgen method.

These lesions have been frequently found in operations upon cases suspected of having calculi in which a negative diagnosis as to calculus had been rendered after the skiagraphic examination.

Calculi in the ureter just outside the bladder may give rise to symptoms that simulate vesical stone, the irritation of the vesical trigone causing, among other symptoms, a referred pain in the glans penis. In a case which illustrated this very clearly the patient had been operated upon and searched for an encysted vesical calculus. The Roentgen examination showed four small calculi impacted in the lower portion of the ureter. Two of them were afterward passed and the others broke down and were removed from the bladder in the form of coarse gravel.

The symptoms are frequently so indefinite, even when a large calculus is present in the calyces or pelvis of the kidney, as to render an absolute diagnosis impossible except by exploratory operation or the Roentgen method. In one case the presence of a calculus in a large pyonephritic kidney was suspected; the skiagraph showed no calculus and an operation confirmed that diagnosis. In another case a branched calculus, one and one-half inches in length, was found in a patient whose only symptoms had been a slight albuminuria and a continued dull ache in the lumbar region. This patient had consulted a number of clinicians, only one of whom had advised exploratory operation. In a similar case, which had, however, a history of having passed blood ten years previously, a small calculus weighing thirteen grains was found and removed. The urine was normal except for a trace of albumin and an occasional pus-cell.

As an effect of the more accurate knowledge

[1] Amer. Medicine and Jour. Amer. Med. Assoc., Nov. 30, 1901.

obtained by this method of diagnosis, an alteration has taken place in the indications and methods of operation. The determination of the exact location, the size, and number of the calculi present, renders rational a conservative expectant line of treatment which, without this accurate knowledge, would have been extremely hazardous. With this knowledge, in cases in which the calculus is found to be of a size that will probably pass, if there is no anuria present, delay under careful supervision is more rational and less dangerous than operation. The Roentgen method is the only means of differentiating between those cases that demand immediate operation and those in which medical or expectant treatment is justifiable. The value of this differentiation has been proved in nine cases in which delay has been advised as a result of the Roentgen examination, and the calculus has subsequently been passed.

The accurate determination of the position and number of the calculi has resulted in limiting the field of operation, and in rendering the intervention more accurate and complete, while it excludes the danger that menaced from the unrecognized involvement of the other kidney or ureter in the calculous disease. It is no longer necessary to perform an exploratory nephrotomy upon the healthy kidney before doing a nephrectomy, or to open a healthy kidney in the search for a calculus that is obstructing the ureter lower down. Incision into the kidney, during an exploratory or any other operation, is only justified by the detection of a calculus by the Roentgen method or an obvious pathological lesion.

A calculus in the ureter can be removed by a direct ureterolithotomy, and the pyo- or hydronephrosis can be cured without direct operation upon the kidney. The failure to detect a calculus in the ureter during a nephrolithotomy has frequently led to the formation of a urinary fistula. Two cases of this character have recently been referred to the author for examination. In both calculi were found the ureter. The presence of multiple calculi in ten cases that have been referred to him for diagnosis renders this procedure an essential to a complete examination. In four of these cases calculi were found in both kidneys after one calculus had been removed at a previous operation.

The accuracy of the negative diagnosis renders it unnecessary to incise the kidneys or ureter in the search for calculi. It renders safe and rational the treatment of renal disease by purely medical measures, when the symptomatology does not point to some cause other than calculus that demands operative intervention. An operation, with its attendant risks, that would otherwise have been essential to the safety of the patient and the integrity of the kidney, is often obviated. It eliminates calculus anuria from consideration, and any operation upon one kidney is free from the danger that the other is the seat of calculous disease. In cases demanding a nephrorrhaphy there is no longer need to search for calculi. The kidney does not need to be opened in the search for a calculus that is in the ureter, or for others when those demonstrated have been removed.

These effects upon diagnosis and treatment, as the result of the employment of the Roentgen method of diagnosis, have been observed in the study of the 206 cases suspected of renal calculus that have been referred to the author for examination. Calculi have been found in 65 cases and in over 60 per cent. they were in the ureter. In only three cases in which a negative diagnosis has been rendered has it been found incorrect. In one case, already reported, the error was due to faulty technic. In the other two cases calculi, weighing less than one grain each, were overlooked and subsequently passed. Other calculi as small have frequently been detected.

The chance of error in the negative diagnosis is, therefore, very slight, and the calculi that may be overlooked are so small that their final expulsion is certain. There are as yet patients in whom it is impossible to make an absolute negative diagnosis on account of their size. In suitable cases hydronephrotic and displaced kidneys have been demonstrated; while calculi have been detected in patients weighing over 200 pounds. In such cases when great detail is demanded in the skiagraph or the difficulties to be overcome are out of the ordinary, it is sometimes necessary to make repeated exposures before a satisfactory result is obtained. When, however, such a result is obtained, it enables the diagnostician to demonstrate the accuracy of his results to those capable of appreciation.

1930 Chestnut Street.

RETINAL LESIONS OF CHRONIC INTERSTITIAL NEPHRITIS.[1]

BY EDWARD JACKSON, A.M., M.D.,
OF DENVER, COLO.

The extremely intimate connection between chronic Bright's disease and certain general degenerative changes in the walls of the blood-vessels is universally recognized. But the true relation between these local renal changes and the general vascular alteration is so imperfectly understood that it is still entirely uncertain which stands in the chain of connection nearer to cause and which nearer to effect, or if both may not arise on parallel lines from common causes as yet unappreciated. The local changes have, by postmortem study and by clinical observation of the urine, been fairly well worked out. But the general vascular degeneration, although its effects on blood-pressure have claimed attention and have been the basis of much fine theorizing, is still extremely obscure. Enough observations have been made upon them to demonstrate that the blood-vessels directly visible within the eye participate fully in the general vascular

[1] Read before the Rocky Mountain Interstate Medical Association, Sept. 3, 1901.

changes. These changes have been thus observed accidentally or incidentally from time to time; but no sufficiently thorough study of them has been made to give any definite idea of the full possibilities of investigation along this line.

Of the general value of the ophthalmoscope, Loring truly said, "With it, it is like walking into Nature's laboratory and 'seeing the infinite in action,' since by its means we are enabled to look upon the only nerve in the whole body which can ever lie open to our inspection under physiological conditions, and to follow in a transparent membrane an isolated circulation from its entrance into the eye through the arteries to its exit in the veins." It is to be regretted that so few physicians especially interested in renal and vascular disease have entered Nature's laboratory through the open door of the ophthalmoscope. Ignorance of the facts of the case seems the most reasonable explanation for the common failure to understand the absolute and relative importance of the retinal lesions of chronic interstitial nephritis.

These lesions include: (1) Alterations in the contour, size, and color of the retinal vessels; (2) hemorrhages and the progressively changing exudates which constitute steps in the removal of effused blood; (3) retinal edema; (4) degenerative changes in the neural elements of the retina and alterations in the layer of pigment epithelium; (5) deposits of exudate which perhaps have a significance somewhat different from that of the foregoing symptoms.

Vascular Changes.—Changes in the capillary circulation and in the smallest arteries and veins cause little or no perceptible change in the appearance of the general fundus. But they do cause striking alterations in the color of the optic disk. To such changes must be ascribed one of the earliest, and perhaps the most constant, ophthalmoscopic symptom of this disease. This is a dirty or brick-red discoloration of the optic disk, which may be compared to the color of a concentrated urine, turbid with urates and uric acid, as seen against a white background. This symptom belongs to the stage of high arterial tension, and may antedate any noticeable alteration in the urine. It probably persists over long periods, with considerable alterations of hue from time to time. This appearance is not well described in the accounts commonly given of these ocular lesions. But I have carefully observed it a number of times, and mention it in this connection with no question as to its significance.

Irregularities of Caliber.—Although not so striking in the arteries as in the veins, these are sometimes unmistakable in the former. Their pathological character is often difficult to establish in any particular case. An artery to start with is not a rigid, machine-drawn tube. More like a running stream, its width varies from point to point, though normally within rather narrow limits. More important are the variations in the shape of its cross-section. An artery at one point may be flattened in the plane of the retina, at another point it may be flattened in a plane at right angles thereto. When seen with the ophthalmoscope, this gives it a narrower contour at one point than at another, although it might have the same sectional area at both points. Still more confusing are the changes in apparent width occasioned by variations in the vascular sheaths, or in other tissues surrounding the artery, the reflexes from the retinal surface, or the crossings of other vessels.

But in spite of these variations, which are constantly to be encountered in the normal eye, we can sometimes make out in the arteries alterations of outline that may be set down with certainty as abnormal. Distinctly sacculated aneurismal dilatations occur, but they are rare. I remember to have seen them, on vessels large enough to be certainly identified as arteries, in but two cases. Notable constrictions and considerable lengths of broadened vessels are more frequent.

Alterations in the contour of veins are much more common. They can be made out in practically all cases of albuminuric retinitis. Generally the most striking alterations are seen in the small veins that arise in the region of the macula. The veins present the same normal variations of contour as the arteries. But the pathological alterations are so much greater as to be readily recognizable. These alterations are chiefly in the direction of dilatation. Sacculated dilatations are much more common on the veins than on the arteries. When relatively large, they may be difficult to distinguish from hemorrhages, especially when other parts of the vein are hidden by a swollen hazy retina.

Changes of Size in the Vessels.—These really include the foregoing changes of contour. It is less common and less characteristic for the retinal arteries or veins to be dilated or contracted as a whole than for them to show the partial changes of size above referred to. Such general dilatation or contraction of the vessels occurs in connection with optic neuritis, the arteries being contracted and the veins dilated as in choked disk from other causes. Usually, in chronic cases, there is a general shrinkage of both arteries and veins, although some parts generally remain dilated.

Tortuosity of the retinal vessels is chiefly a sign of dilatation. A distended blood-vessel enlarges in all directions. It not only becomes broader, it becomes longer; and its increased length forces it to leave the comparatively straight course for one curving back and forth. Marked tortuosity of the retinal vessels occurs as an anomaly. As an anomaly, it is more likely to affect all of the retinal arteries or all of the retinal veins; still it may be most marked in, or wholly limited to, a single vessel. Tortuosity, as an anomaly, is more likely to be confined to the plane of the retina, the different curves of a vessel lying at the same depth, having the same refraction. Pathological tortuosity shows

greater variations of depth of the different parts of the vessels. The curves are toward and from the center of the eyeball, as well as in the plane of the retina. But the most certain guide to the character of the tortuosity is the co-existence of other retinal lesions, particularly the irregular venous dilatations.

The alterations in the color of the vessels may be due wholly to the character or to the amount of their contents. The dilated veins look dark. Extreme anemia causes all the vessels to appear pale. But changes in the vessel-walls may also produce changes of color. The most striking of these are those due to opacity of the walls concealing the contained blood-current. The vessels are often yellowish from such opacity. In a good many cases the gray or whitish line along each side of the vessel which is often seen in normal eyes upon the disk may be found extending far out into the retina or it may attend some limited part of a vessel quite removed from the optic disk. A more rare, but more striking condition, is that in which the vessel becomes an opaque brilliant white, through fatty degeneration. In one case that I saw with Dr. George C. Harlan of Philadelphia, who reported it to the American Ophthalmological Society[1], every retinal vessel in one eye, except one minute branch, presented the appearance of a brilliant white streak or band. Usually, however, such an appearance is confined to a single vessel or to limited patches in one or more vessels. Such patches may be found, without any evidence that the passage of blood through that part of the vessel is interfered with.

Retinal Hemorrhage is pretty constantly present among these retinal changes of chronic interstitial nephritis. But in most cases there are times when no hemorrhage will be found upon ophthalmoscopic examination. Mostly the hemorrhage spreads sufficiently in the nerve-fiber layer of the retina to give it the usual flame-shape. But smaller rounded dots of effused blood are frequent; and when they occur without much edema and without opacity of the retina they are readily overlooked. Very large hemorrhages are rare in the condition specially under consideration. They are more apt to attend the toxic exudative form of disease. How long any particular retinal hemorrhage will be recognizable as a hemorrhage is always uncertain. Small hemorrhages may remain apparently unchanged for several weeks. In other cases large ones wholly disappear in a few days. Rapid and complete disappearance is probably a favorable sign.

The symptoms thus far discussed—the changes in the appearances of the vessels and hemorrhages—are clearly dependent upon alterations of the vessel-walls. They are the retinal expression of the general vascular degeneration which seems to be an essential part of this disease. The edema and degenerative changes in the retina proper are so constantly associated with the above changes that it is reasonable to suppose they have the same origin.

Edema of the Retina is usually localized, at least it is much more marked in some parts of the retina than in others. In the affected patches, the color is lighter and more gray than that of the normal fundus. Sometimes it is wholly gray, with no trace of the normal fundus red. In these patches the retinal vessels are more or less hidden, except the parts that come fully up to the surface of the retina, which become more noticeable by reason of the strong contrast of their gray background. A small knuckle of dilated vein appearing thus upon the surface, while the remainder of the vessel is hidden by opacity of the swollen retina, may look exactly like a small hemorrhage. Apparent small hemorrhages in the midst of the retinal edema must, on this account, be carefully examined before they are passed upon. Close inspection may show the affected vessel entering the opaque patch.

Degenerative Changes in the Retina.—The brilliant white patches due to fatty degeneration in the retina are the most striking ophthalmoscopic symptom of chronic interstitial nephritis. They probably always appear in a case that runs a complete course. Such a patch may follow and arise from a retinal hemorrhage; it may be a late stage in the history of a mass of exudate; or it may follow a localized edema. But smaller patches, and even those of medium size, may arise without any evident preceding lesion. So that they seem to have a direct relation with the underlying vascular change or its essential cause. Such spots are not peculiar to albuminuric retinitis. They are found in connection with optic neuritis from brain tumor; are a leading feature of diabetic retinitis; constitute the characteristic wreath of retinitis circinata, and sometimes appear in retinal thrombosis and in leucemic retinitis. Yet the first thought on finding such patches should be of the renal-vascular disease. Their arrangement in radiating lines about the macula, certain bundles of nerve-fibers being affected at different points, while others remain intact throughout, is the typical arrangement. But this grouping may be quite wanting without throwing any doubt on the diagnosis. A few times I have found these spots chiefly in the periphery of the retina. When this was the case the spots were all small. Large patches appear only near the disk or macula.

These white spots, it would naturally be inferred, are of comparatively late and slow development and somewhat permanent in character. But some are almost always found at the first examination of the case; and last year W. A. Martin[1] reported a case seen when vision was first impaired, in which exudates began to appear in ten days, and in the course of three weeks a perfect halo characteristic of albuminuric retinitis had developed at the macula. Nor are such patches entirely permanent. They may often be

[1] Transactions for 1896, page 190.

[1] Ophthalmic Record, July, 1900.

seen to diminish, their outlines becoming more indefinite; and in cases that persist for a long time, they may wholly pass away.

The degenerative changes in the pigment epithelium are mostly secondary to hemorrhage, or to a distinct inflammatory process in the overlying layer of the retina. They include sharply localized atrophies and masses of pigmentation. That more generalized changes in this layer occur is not unlikely, but they have not been carefully studied.

Masses of Exudate.—The large masses of exudate found near the optic nerve entrance and posterior pole of the eye, in some cases, are on the one hand related to hemorrhage, on the other to edema, and they may become the origin of the white spots. They are however seen especially in albuminuric retinitis due to acute nephritis and to pregnancy. In chronic interstitial nephritis I have met them chiefly in cases in which toxemia was strongly marked. This might be coincidence, but it suggests an origin from something besides vascular degeneration. The exudate causes swelling of the retina to several times its normal thickness, and disfigures the fundus with dirty reddish-white blotches, which may obliterate the usual landmarks of the eye-ground, even the optic disk. These masses may embed or hide the other changes in the retina. They are liable to great changes of form and amount and may be entirely removed.

Associations of the Retinal Lesions.—As has before been indicated, these retinal lesions are very closely associated with vascular changes. I have never seen them approaching a typical development, but in conjunction with vascular rigidity; except the hyperemia first mentioned. In the great mass of cases they appear just when the prolonged high vascular tension begins to be insufficient and elimination is failing. The association with vascular degeneration is more constant than association with albumin in the urine, casts of any form, or any other clinical evidence of renal disease. It is this association that gives these lesions their unique prognostic significance. They appear when the balance of blood-pressure and matter to be eliminated has been lost, and give most positive notice of a state of nutrition that cannot very long continue. If "a man is as old as his arteries," these evidences of arterial degeneration tell in unmistakable language that his race is nearly run.

Prognosis.—Accumulated statistics now including many hundreds of cases, brought together from all parts of the world, show that a large majority of patients presenting these lesions die within a year after they are first discovered. Belt brought together some 419 cases and found that 72 per cent. were fatal at the end of the first year, and 90 per cent. within two years. The cases reported from Haab's practice by Possauer are even more instructive. Of men applying at his clinic all were dead within two years. Of the women coming to the clinic 32 per cent. survived that period. But among private patients who could live comfortably, only 59 per cent. of the men died within two years, and of the women only 53 per cent. These figures, which are to a large extent supported by the experience of others, give a strong indication as to the proper management of these cases, and the especial dangers that threaten to terminate the life of the patient suffering from chronic interstitial nephritis.

Conclusion.—In the foregoing account special emphasis has been laid upon the close relation between these retinal lesions and the degenerative changes in the walls of the blood-vessels. Whether the vascular changes cause the retinal lesions, or whether their connection is that both spring from a common cause, the retinal symptoms take from this close connection great importance. They throw light upon what goes on in the central nervous system, and, modified *pari passu*, in other organs of the body. Whether considered as a means of understanding the essential nature of this disease process, or as throwing light on the character and course of the individual case, they have an importance that the mass of physicians very imperfectly appreciate.

EXOSTOSIS OF FEMUR DUE TO TRAUMATISM.[1]

BY W. R. TOWNSEND, A.M., M.D.,
OF NEW YORK.

A MUSCULAR young man of twenty-five years of age while playing football on February 12, 1901, collided with another player and was struck across the right thigh by the other man's knee. An immediate effusion followed into the knee-joint. The patient was seen by Dr. Kimball, who very properly applied a plaster cast and kept the knee at rest. This treatment was continued for three weeks, and at the end of that time the swelling had subsided and the knee synovitis was apparently cured; but, to make certain that the knee would not be damaged, a plaster cast was reapplied and left on for another three weeks, when the knee was found to be free from fluid, straight, and flexion restricted to about thirty degrees; above the joint was found a hard mass. The patient was then referred to me.

An examination showed the knee-joint free from fluid. The knee could be fully extended, but could not be flexed more than thirty degrees. No pain or tenderness about the joint. About two inches above the knee was a hard mass four inches long and apparently attached to the femur. Deep pressure gave slight pain. The right thigh measured seventeen inches four inches above the patella, the left measured eighteen inches; the right thigh, six inches above the patella, eighteen and one-half inches, the left, nineteen and one-half; the right thigh, nine inches above the patella, nineteen and one-half, the left twenty and three-quarter inches. The restriction of motion in the knee seemed to be due to the presence of

[1] Patient, radiograph and specimen presented at meeting of Clinical Society of New York Polyclinic, Nov. 4, 1901.

this mass, rather than to any condition within the joint. The quadriceps could not be fully stretched, and when an effort was made to bend the knee, the patella could not slide downward.

The diagnosis lay between an exostosis, a sarcoma or a myositis ossificans. Sarcoma, although it does occasionally develop with great rapidity, was thought to be the least likely diagnosis, as the man's condition was so perfect. There was no pain and the injury which caused this growth was received less than two months prior to my examination.

Two X-ray pictures were taken. An anteroposterior view shows absolutely nothing of the tumor. A lateral view shows little patches of darkness in the muscle, and a perfectly clear, clean edge to the femur. It does not show any connection between the femur and the bony tumor. Owing to the short time that the bone had been forming, it was not expected that the shadows would be any darker than they were. From this picture I was rather inclined to the diagnosis of myositis ossificans, but examination after removal of the tumor showed that it was an exostosis.

Exostosis of Femur.

Operation was performed April 9, 1901. An incision about four inches long was made along the anterior surface of the thigh, directly over the tumor. It was removed without any difficulty. Care was taken not to enter the synovial sac above the knee-joint, as the lower end of the tumor infringed on it. The tumor was entirely dissected out, with some of the muscle. It was found attached to the periosteum and not to the bone. The wound healed *per primam,* the man's temperature never went above 99° F., and he made a complete and rapid recovery. On May 15th he could bend his knee forty-five degrees; on May 22d, fifty degrees; on May 27th, fifty-five degrees; on June 4th, ninety degrees, and he is now able to move it through an arc of about one hundred and twenty degrees. The scar is not adherent, and he is able to resume his occupation, which is that of a professional tennis player.

The microscopical examination made by Dr. Jeffries of the Polyclinic Laboratory shows the following: The bone tissue removed from thigh of patient in the Polyclinic Hospital April 9th has been submitted to microscopical examination, and its nature determined as an exostosis. It is unassociated with the muscular tissue removed, other than by continuity. The two tissues are at all points separated by a thin layer of dense fibrous tissue of the white, inelastic variety. This fibrous capsule (?) is not a well-defined band, but gradually diminishes in density in either direction toward bone and muscle. The muscular tissue adjacent to the fibrous has to a certain extent been displaced by fibrous tissue, as muscular fibers with all degrees of atrophy are found embedded in the latter.

There is no sign of acute inflammation; the changes are all of a proliferative or formative nature. The bone tissue is of the cancellous variety, some of the trabeculæ of which contain cartilage. The marrow is a very loose fibrous tissue, richly supplied with blood-vessels of capillary and cavernous varieties. The cells are scant, and are arranged within the meshes of very delicate fibrillæ. They are generally spindle-shaped, but with an admixture of small mononucleated (lymphoid) cells. The surfaces of the trabeculæ are beset with a layer of osteoblasts and here and there a multinucleated osteoblast is observed. The measurements are 9 centimeters by 4½ centimeters by 2 centimeters.

MEDICAL PROGRESS.

PEDIATRICS.

Unnoticed Fractures in Children.—The overlooking of fractures is especially likely to happen in children, not only because they are less exact in their complaints, but because many fractures in children show disproportionately little pain or reaction. Even if the fracture be complete the child is often surprisingly tolerant. A series of 18 cases of fractures in children, in which diagnosis was confirmed by the skiagraph, is reported by F. J. Cotton and R. H. Vose (Boston Med. & Surg. Jour., Jan. 9, 1902), who suggest certain diagnostic points. In examining these patients there may be no complaint of pain, but some difference in the use of the limb of the two sides may be noticed. In some cases this is due to reflex muscular spasm of the same sort as is seen in joint disease. Illustrations are the limp associated with certain fractures of the tibia and the loss of grasp in green-stick fracture of the forearm; again, in fracture of the clavicle, if the child be asked to raise both arms he lifts one hardly more than half as high as the other. Passive motion in these cases may or may not be painful. If painful, the pain is felt only on extreme flexion or extension. Local tenderness may be slight, but is always present. Careful palpation may reveal deformity and now and then wholly unexpected crepitus is found. When days or weeks have elapsed a well-defined (often ring-like) callus is palpated. In treating the cases upon which their report is based, the writers obtained practically perfect results by simple fixation for from two to four weeks.

Enlargement of Bronchial Glands.—Although this is undoubtedly a comparatively frequent condition in

childhood, it is probably very seldom diagnosed because physicians are too careless in making physical examinations. D. McM. Officer (Inter. Med. Jour. of Australasia, Dec., 1901) says that it may be recognized by the presence of dulness in the interscapular region of one side, together with diminished breathing over that side of the chest. The latter sign results from the pressure of the glands upon the bronchi and consequent narrowing of the lumen. The most frequent cause of the enlargement of these glands is tuberculosis, and in children pulmonary tuberculosis is usually secondary to the enlargement of these glands. A chronic bronchopneumonia follows and, in contrast to adult tuberculous lesions, the signs are infrequently found at the apices. The early recognition of these glands at the root of the lung, therefore, becomes of prime importance. Influenza and measles are also causes of such glandular enlargement, but the enlargement is seldom so persistent as in the tuberculous cases.

Regulation of Food in Childhood.—Although the infant presents most difficult problems to the physician in regard to the proper modification of milk in the early months, and although so much has been written about the feeding at this time, one should not forget the importance of an intelligent supervision over the subsequent change of diet from milk to a more general one. J. E. Winters (Med. Rec., Jan. 25, 1902) shows that there are a rapid development and a marked functional activity of the glands which secrete the diastasic ferments from the seventh to the tenth month, depending upon the degree of development of the child and the advancement of dentition. This shows the need for more farinaceous food and among the most valuable of these is oatmeal, which contains a large percentage of iron, proteids, fat and mineral matters, the constituents most essential for the development of the child. On account of the cellulose present, oatmeal should be well cooked and drained, and a half ounce of oatmeal jelly may be added to each second feeding. At the end of the first year a soft-boiled or poached egg mixed with bread crumbs from stale bread may be added to the diet. The nuclein of the yolk is especially valuable on account of the iron and phosphorus. Only a small quantity twice a week should be given at first. A hard crust which will necessitate vigorous chewing is useful at this time. At the end of fifteen months a child should get whole milk, oatmeal or barley, soft-boiled eggs twice a week, crusts of bread twice a day and perhaps a little bread and milk. Cereals should be given without sugar, as the latter causes constipation by the large amount of water required to keep it in solution. Orange juice and prune pulp are the first fruits for a child and are especially good in cases of constipation. They are given one hour before meals. The growing child needs large quantities of mineral matter to build up the bony framework, but this must be in the form of organic combination with proteid substances. Raw milk, eggs, cereals and certain fresh vegetables furnish mineral salts in organic combination ready for assimilation. The mistake is often made of giving too much meat and meat extractives, which stimulate metabolism and really prevent laying on fat or muscle tissue, on account of their overstimulating action. Carbohydrates are easily oxidized and their oxidation serves to protect the proteids and fats from consumption. The shielding of these requisites for the growth and development of new structures is a matter of profound value and consequence to a growing child. During all the years of early childhood meat and its preparations should be given sparingly, for they also create a distaste for cereals, fats, and fresh vegetables, thus depriving the system of materials needed to shield the proteids from oxidation. To provide mineral constituents necessary for the growth of bone and muscle, vegetables which contain these substances fresh from the soil must be consumed in fairly liberal proportions.

Infant Incubation; A New Incubator.—There are four main problems in incubator work, (1) heating apparatus; (2) ventilation; (3) moisture; (4) portability and simplicity, neither of which can be obtained except at the expense of ventilation. A new incubator embodying desirable features is described by J. B. De Lee (Chicago Med. Rec., Jan. 15, 1902). The first and most important indication for the use of the couveuse is prematurity; infants are regarded as premature if they are born sooner than three weeks before term, if they weigh less than 5½ pounds, or measure less than 46 centimeters. Infants evidently premature should be put at once in the incubator; it may not be necessary to keep them there more than a few days, but the protection is especially needful during the first few hours. Congenitally feeble infants should be treated as premature; they may be of fair size, but have subnormal temperature, cyanosis or tendency to edema or sclerema. After difficult operative delivery even a full-term baby may be in a condition of shock; Lee would limit energetic measures for the revival of such infants and would place them as soon as possible in the incubator. Melena neonatorum and all congenital hemorrhagic manifestations, *e.g.*, hemophilia, multiple hemorrhages, morbus maculosis Werlhofii, are regarded as indications for the incubator. Two such cases with recovery are recorded; one had melena with eight profuse hemorrhages, the other hemorrhages from the nose and mouth and into the skin. At the Chicago Lying-In Hospital the temperature of the incubator at the outset is usually 89° F.; when the child is larger and ready to leave the incubator the thermometer is set successively at 86°, 84° and 82° F. The punier the infant, the more moisture needed; thirty to fifty degrees is a proper range. The dress of the incubator infant is all wool. Without mother's milk it is almost impossible to raise a premature infant. Artificial feeding has been abandoned; mixed feeding is somewhat better. The incubator infant needs at first no baths; it should be anointed daily with benzoinated lard. After ten days it may be bathed in water at 103° F. in a warm room. Daily massage and passive motions must be practised, with extreme gentleness at first. When the infant's temperature remains normal for days and when the child weighs about 4½ pounds, it is removed to its cradle. The period of incubator life varies from five days to four weeks. Operative cases are removed when they have recovered from the shock of the delivery. At the Chicago Lying-In Hospital 28 babies have been placed in the incubator in two years. Of these, 8 died in a few hours (these were usually frozen or in convulsions on arrival at the hospital); 3 had hemorrhagic diathesis; 2 died of atelactasis pulmonum; 1 lived four days, and 14 were reared and discharged well. Of the 14 that died, 2 were in the sixth month, 7 in the seventh month, 5 in the eighth month. Of the 14 that were saved, 2 were in the sixth month, 4 in the seventh month, 8 in the eighth month.

Primary Abdominal Tuberculosis.—Several recent papers upon this subject have expressed the belief that primary lesions of tuberculosis within the abdominal cavity were very rare, and the authors have urged this fact against the communicability of bovine tuberculosis to man. A. Jacobi (N. Y. Med. Jour., Jan. 25, 1902) expresses the view that even the few undisputed instances in which the disease has been shown to have been acquired by children feeding on milk from tuberculous cows are sufficient to make one extremely careful in regard to the use of any suspected milk. Furthermore, he believes that primary abdom-

inal lesions are much more common than is ordinarily thought. Primary tuberculous ulcerations of the intestine are seldom found, and when they are found they are mostly connected with pulmonary lesions, usually of a mixed type. Not less rare is primary tuberculosis of the mesenteric glands, but peritoneal tuberculosis is very frequent and he believes that it is due to the passage of the tubercle bacilli through some slight or transient lesion of the mucous membrane or even through a normal inner coating of the intestine.

Acute Articular Rheumatism in an Infant.—Beginning in the left elbow which was swollen, red and very tender, rheumatism attacked in succession the left wrist, knee and ankle, right knee, ankle, elbow and wrist of a child twenty-seven days old. On the sixteenth day the temperature was normal, but the pulse remained 150, though the inflamamtion in all the joints but one elbow had subsided. The treatment instituted by P. J. BARCUS (Archives of Pediatrics, Jan., 1902) was 0.06 gm. (gr. i) each of bicarbonate and salicylate of sodium every three hours three times a day, and there was no stomach disturbance whatever. One month later the right knee was again swollen, but this subsided in a week. After complete subsidence of the joint affections, the infant slowly gained weight, the heart showing nothing abnormal on auscultation, but continuing to beat at 125.

The Malnutrition of Tuberculosis.—A study of this condition is briefly summarized by F. M. CRANDALL (Arch. of Pediatrics, Jan., 1902). Wasting, anemia and other evidences of malnutrition may occur in infants long before any local disease can be detected. The disease may run a course identical with marasmus, especially if disseminated or involving only the lymph-nodes. The anemia is usually a simple anemia, and any anemia in adolescents increases the danger of tuberculous invasion. In some cases a period of anemia and wasting is followed by irregular fever and later by signs of lesions in the lungs; but in other cases the local lesions appear first, especially pneumonia. Persistent and increasing malnutrition in a child without discoverable cause is always suggestive of tuberculosis.

Double Sacculated Empyema.—A case of this kind in which a high temperature, unaccounted for by physical signs or rational symptoms, persisted for three months is reported by L. E. HOLT (Archives of Pediatrics, Jan., 1902). The spleen was much enlarged and, though repeated examinations failed to discover malarial organisms, quinine was given but without effect. After a few days a few râles were noted in the lungs, and on the ninth day the right upper lobe gave signs of consolidation. These signs soon disappeared, but nearly always thereafter there could be heard coarse râles, occasional friction sounds, and rude breathing. The temperature continued, the Widal test proved negative, and the leucocytes numbered 28,000. The sputum was negative. The child, boy of two and a half years, was steadily wasting, having all this time had a persistent diarrhea. During the last week of his illness the temperature fell to nearly normal, and remained so until death. There was no displacement of the heart at any time, no vomiting, no cerebral symptoms. The autopsy revealed a small sacculated empyema, containing one or two ounces of thick creamy pus, in each lung. One was situated on the diaphragmatic surface of the right lung and the other near the base of the left lung and close to the spine. There were interstitial bronchopneumonic areas in the right upper lobe and ulcers in the colon.

Acute Hemorrhagic Nephritis Complicating Influenza.—In an analysis of forty cases of this complication D. J. M. MILLER (Archives of Pediatrics, Jan., 1902) found it to occur eighteen times in cases under sixteen. The onset is usually early; hyaline, epithelial and granular casts are present, and sometimes blood casts, and the albumin is generally abundant. The urine was mostly scanty. Edema was observed in less than half of the cases, fever in about half. In most the duration of the disease was less than a month. The kidney lesions are those of an infectious or toxic nephritis the type of which is the scarlatiniform.

HISTOLOGY, PATHOLOGY AND BACTERIOLOGY.

Insects and the Spread of Disease.—In an interesting and instructive article, J. MCFARLAND (Medicine, Jan., 1902) reviews the change in attitude toward certain insects, whereby those once thought merely annoying are now considered disseminators of disease. Insects may carry on their bodies disease-producing microbes and occasion infection by alighting upon wounds or indirectly by alighting upon foodstuffs. They may carry within their bodies germs which may subsequently be deposited with their feces; tubercle bacilli have been detected in the feces of flies fed on tuberculous sputum. Suctorial insects by biting a diseased animal may carry infection to the next animal bitten. They may take infectious germs into their bodies and transmit them to their offspring, bites of which are infectious. Insects may take in parasitic organisms and transmit them to other animals in some, changed form in which they are infective, for example, the change of the malarial organism in the mosquito's alimentary tract, the formation of "blasts," and their escape with the salivary secretion when the insect bites. In like manner is yellow fever transmitted, this transmission not being direct, but requiring an interval of ten days before the mosquito's bite is infectious. A third disease transmitted by the mosquito is filariasis. Insects, such as flies and roaches, may become infected, die, fall into foodstuffs, and thus impart infection to man. Flies have been known to die from the infection of bubonic plague.

New Method of Isolating Typhoid Bacillus.—An attempt was made by CAMBIER to isolate the bacillus typhosus upon the theory that it alone would pass through a porous earthen filter. U. BIFFI (La Rif. Méd., Jan. 3, 1902) has proven that the bacterium coli not infrequently passes through the porous diaphragm simultaneously with or prior to the bacillus of Eberth. To overcome this objection, the writer suggests that, previous to filtration, the substance to be examined for typhoid bacillus be introduced into bouillon to which has been added a serum which will agglutinate the bacterium coli; by this means the bacillus typhosus alone will pass through the diaphragm. The agglutinating serum for the bacterium coli may be readily obtained by following the method of Pfeifer in the preparation of agglutinating serum for the bacillus typhosus, care being exercised to inject simultaneously into the rabbit which is to furnish the serum different varieties of the bacterium coli, so that a serum may be obtained which will equally well agglutinate all varieties. The quantity of serum to be added to the bouillon depends naturally upon its agglutinating power; hence it is well to make several tests in order to obtain the proper dilution.

Effect of Quinine on Plasmodium Malariæ.—An exhaustive study of this subject has been made by D. LO MONACO and L. PANICHI (La Rif. Méd., Jan. 2 and 3, 1902) in which the effect upon the plasmodium of solutions of quinine bisulphate in various degrees of concentration has been carefully noted. Microscopical examination of freshly-prepared blood specimens demonstrated reaction of the plasmodium to a drop of the solution, placed upon the margin of the cover glass,

proportionate to its strength; weak solutions producing excitation and emission of pseudopodia, stronger solutions causing detachment of the parasite from the red blood-cell. The youngest, non-granular forms of the plasmodium proved to be the least influenced. The practical value of these observations rests upon the determination of the strength of solutions necessary to effect such detachment in the various forms of the parasite; in the authors' experience, a dose of quinine, equivalent in strength to the solution causing this phenomenon, administered to a patient, was sufficient to cause disappearance of malarial paroxysms. Acting upon this, an attempt has been made to establish a rational dosage in each type of malarial infection. Clinical observation also showed that a smaller dose was necessary to prevent recurrence of paroxysms, if administered at the onset or height of pyrexia, than when given between paroxysms; the supposition being that antiparasitic substances which supplement the effect of quinine circulate in the blood during pyrexia.

Glycogen and Glucose in Muscles after Death.—After reviewing the literature of this subject, and quoting conclusions drawn by various observers, notably those of Lacassagne and Martin, who hold that the presence of both substances indicates rapid death due to violence, the absence of both slow death not due to violence, and that the presence of glucose without glycogen points to sudden death after prolonged illness, C. CURINI-GALLETTI (Gazz. degli Osped., Dec. 29, 1901) gives the results of his own investigations as follows: (1) Glycogen is found in both muscles and liver, in greater quantity after death by violence than after slow death; this is true, though not to the same degree, of glucose; therefore, the quantitative estimation of glycogen is of greater value than that of glucose in the differentiation of the mode of death. (2) Estimation of glycogen and glucose in the liver yields more positive indications as to the manner of death than estmation of those substances in the muscles.

Angiosarcoma of the Clavicle.—This group, first described and named by Kolaczek, is well represented in the description of a large specimen recently removed from a girl of sixteen by G. T. BEATSON (Brit. Med. Jour., Jan. 18, 1902). The surgicopathologic history of the case is as follows: In seven months a swelling, the size of an infant's head developed in the region of the left clavicle. The patient could assign no cause for its appearance; it began as a small tumor which was freely movable beneath the skin; it gave no symptoms save one of alarm from its great size and rapid growth. On palpation it was firm and elastic, almost cystic in character. There was neither fluctuation nor pulsation. It was firmly anchored at its base, but it gave no pressure symptoms. A skiagraph of the parts showed that, with the exception of a small part at its outer end, the left clavicle had disappeared. Operation confirmed the diagnosis and the patient made a good recovery. The gross pathology of the neoplasm was as follows: It was a globular mass, flattened anteroposteriorly. It measured 5½ by 3 inches and had a fairly-marked capsule to which masses of fascia and muscle were adherent. On section it was "fleshy." The microscopical examination of the mass showed it to be sarcomatous and of the round-celled variety. The very striking and peculiar characteristic, however, was the presence in each group of cells, and generally in the center of it, of one or more well-marked blood-vessels around which the cells are arranged concentrically. The very intimate relation of cell to vessel in the sarcomata is well known; some pathologists go so far as to say that all such neoplasms take origin in the blood-vessels. However this may be, there is undoubtedly a variety of sarcoma characterized by masses of round cells and springing from the adventitia of the vessels around which they are grouped. In this small group, as in the present case, the endothelium is entirely normal; this fact clearly distinguishes it from the better known endotheliomatous sarcomata. By the mechanics of their growth the angiosarcomata present a more or less constant alveolar structure. They are occasionally melanotic and suffer the usual degenerations. The after-history of the case will be interesting. Six months after removal some small glands were removed from the region of the scar, but while sarcomatous in type they were diagnosed as inflammation, largely because of the continued good health of the patient. Metastasis in the angiosarcomata, except when they are pigmented, is rare, but opinions as to the probability of local recurrence differ; Senn states that after-growth is very rapid; Stengel that it is very rare; the tumors are classed by him as in a measure benign. This case, so far, supports the latter view; two years have passed since the operation and there are no signs either of metastasis or of local recurrence.

OBSTETRICS AND GYNECOLOGY.

Early Ectopic Gestation.—That the three classical gross symptoms of ectopic pregnancy, *i.e.*, pain, hemorrhage, and pelvic tumor, are not the essentials of an early ectopic gestation is shown by E. K. BROWD (Phil. Med. Jour., Jan. 18, 1902) in a series of cases observed by himself and others. His own six cases were all less than six weeks pregnant and the symptoms of pain and tumor were entirely absent, the only sign being an untimely oozing of blood from the uterus. As pain is the result of an overfilled and pathological condition of a tube and takes place usually when adhesions are formed, it is not apt to come on until the later stages, the third month or more. The local tumor also indicates an advanced stage. The oozing of blood entirely depends on the location of the ovum in the tube; the flow may escape by the fimbriated extremity into the abdominal cavity and so give no external evidences. It may also be stated that not every interrupted hemorrhage from the uterus speaks for the existence of an extra-uterine pregnancy, but may be caused by a pus tube, cystic disease of ovary, imperfect abortion, polypoid endometritis, etc. In discussing the treatment, the analogy is drawn between early ectopic gestation and suspected appendicitis, as in the latter case the best results are obtained by early interference. So bearing in mind the comparative safety of exploratory laparotomies, he recommends that in every suspicious case of extra-uterine pregnancy operation be done when its existence is quite positively known, and also in cases in which dark and baffling symptoms may cause doubt as to its presence.

Decreasing Fecundity.—The progress of medical science in general is shown in the control of infectious diseases and a decrease in the death-rate. Although a like positive result ought to be expected from the progress of obstetric and gynecic science, this is not the case, but the rate of sterility and the number of miscarriages are increasing and the birth-rate is growing steadily less, particularly in this country. These rather startling facts are made the subject of a paper by G. J. ENGELMANN (Phil. Med. Jour., Jan. 18, 1902). From a collection of available statistics he finds a decreasing birth-rate in all European countries, lowest in France; about the same or even less in the United States, far below that of France for the American born of this country, much higher for the foreign born (2½ times). The American statistics are based on those of six States, others being incomplete. These figures, however, are relatively correct. Although the fecundity of the American-born woman is lower than that of the

woman of any other country, it is found that intermarriage with a foreign male yields a higher fecundity than with an American husband. The causes for such decrease are found principally in the present social conditions which inspire various methods of prevention of conception and family limitation. Health is far more common as the badge of motherhood, while early exhaustion and premature decrepitude are much more likely to issue from the various methods resorted to for the avoidance or prevention of conception. The author believes that the latter are factors more potent in the causation of decreasing fecundity than is the progress of gynecic science for the contrary.

Adhesion of the Placenta.—This is always a troublesome and often an unexplainable condition in childbirth. A. NORDMANN (Arch. f. Gyn., Bd. 65, Heft 1, 1901) presents the following conclusions upon the subject: The presence of anatomical changes as the cause of the adherence of the placenta is beyond all question. There are, at the present time, two types of this adherence. The first type depends upon changes in the decidua serotina. The second type is caused by a growing together of the muscular tissue of the uterus and the uterine surface of the placenta. The cause of the serotinal form seems to depend upon injuries of the mucous membrane of the uterus, such as repeated separation of the placenta, the application of caustics, etc. The muscular form is probably the most common and is very likely due to a variation in the normal insertion of the organ upon the uterus.

Tuberculosis of Female Genital Organs.—Deductions from an extended study of this subject are tabulated by C. MERLETTE (Arch. d. Ostet. e Gin., No. 12, Dec., 1901) thus: (1) Tuberculosis of the genital organs is more frequent in women than in men; (2) this preponderance in the female is partly due to the closer relation between the genital organs, peritoneum and intestines, partly to infective causes due to functions of generative life; the condition is rare before puberty and after the menopause; (3) it is generally secondary, but may be primary; (4) tuberculosis of the uterus is more frequent than is generally supposed; (5) genital hypoplasia predisposes to tuberculosis; (6) cervical tuberculosis may be miliary, catarrhal, or ulcerative; (7) tuberculosis of the body of the uterus occurs in three forms, endometrial, interstitial and mixed; (8) demonstration of the bacillus in uterine secretions is rarely possible; (9) diagnosis by curettage is conclusive only in endometrial tuberculosis, the scrapings showing giant cells and tuberculous follicles; (10) of great semiological value is the injection of uterine secretions into animals, both in tuberculosis of the uterus and in salpingitis; (11) the tubes are especially prone to tuberculous infection; (12) tuberculous salpingitis is almost invariably bilateral; (13) there are three forms of tuberculous salpingitis; peri- and endosalpingitis, and parenchymatous; (14) nodules in tubal isthmus are not pathognomonic of tuberculosis, but frequent in this condition; they are often congenital or may originate in chronic salpingitis; (15) the ovaries show a certain resistance to tuberculosis; (16) more than one-half of tuberculous ovaries become cystic; (17) tuberculosis seems to originate in the stroma of the ovary and not in the ovisacs; (18) of value in the diagnosis of genital tuberculosis is digitorectal examination, which sometimes reveals a granular or nodular condition in the cul-de-sac of Douglas and about the recto-uterine ligaments; (19) consideration of the patient's general condition and history are important to the diagnosis.

Ovariotomy During Pregnancy.—This is an operation which occasionally is necessary. E. ORGLER (Arch. f. Gyn., 1901, B. 65, H. 1) gives an exhaustive study of the subject and states the following facts concerning its effects on the mother and child: The mortality of ovariotomy during pregnancy is not greater than at any other time. Some authors state that interruption of pregnancy by abortion or by untimely birth and by death of the mother occurs in perhaps 22½ per cent. of the cases. That means that in every four or five operations an unfortunate result may be looked for. Permanent damage to the mother is very rare, abnormalities of childbirth ascribable to the operation have not been noted. The earlier the operation is done, the better the results will be as a rule. So far as the immediate results are concerned, it appears to make no difference whether one or both ovaries are removed. Vaginal ovariotomy is as a rule not to be undertaken during pregnancy.

Puerperal Septicemia.—The frightful mortality which has attended these cases led the American Gynecological Society in 1898 to appoint a commission to investigate and propose some line of treatment. W. R. PRYOR (N. Y. Med. Jour., Dec. 25, 1902), a member of this commission, has analyzed all the cases which have occurred during the past five years and gives some very striking views. All cases may be divided into the saprophytic and septic types. In the former cases the infection is always superficial, is accompanied by only moderate fever, and carries no risk to life; but, inasmuch as this form of infection renders the patient susceptible to the implantation of more virulent germs, saprophytic infection has a great importance and demands treatment of a preventive nature. Therefore, the dead material within the uterus must be removed. About seventy-five per cent. of cases are non-septic and about twenty-five septic, so that curettage is indicated in about three-fourths of the cases. The best authorities upon the treatment of the septic cases believe that no local treatment should be applied to the uterus, for the infection is deep within the uterine tissue and cannot be removed by simple curettage. Interference merely increases the area of infection and can only do harm to the patient. Williams and Krönig report a mortality of only five per cent. in septic cases and they never treat the uterine cavity. It, therefore, becomes important to determine in a given case whether the infection is saprophytic or streptococcic; this can be done usually by bacteriological examination, if the clinical symptoms are obscure. A saprophytic case demands curettage, but a streptococcus infection is greatly endangered by such a procedure.

Lumbar Anesthesia in Obstetrics.—The advantages of anesthesia of the entire region below the umbilicus in labor are not to be denied, says C. S. GAUTIER (Rev. Méd. d. Canada, Jan. 1, 1902). Anesthesia lasting two hours may be produced by spinal injection of one centigram of cocaine; points in its favor, aside from the analgesia produced, are said to be as follows: The patient is more easily managed; the soft parts, perineum, etc., are less exposed to laceration; uterine contractions are stronger and more frequent; and danger of hemorrhage from uterine inertia is reduced to a minimum. The intensity of uterine contractions induced by intra-arachnoid injection of cocaine constitutes a contraindication to its use in pregnancy before term. The pros and cons of spinal anesthesia, as shown by the experience of obstetricians and surgeons, are set forth with an apparent preponderance of opinion in its favor.

THERAPEUTICS.

Heliotherapy in Pharyngitis.—The solar rays have been utilized in the treatment of pulmonary and leprous tuberculosis; the simplicity and economy of this method of treatment are points in its favor, although its dependence upon weather conditions pre-

vent its more general use. Forns (Rev. Esp. Med., Dec. 20, 1901) has met with most encouraging results in the treatment of pharyngitis by this method, both in acute and chronic cases. The patient is directed to hold the mouth open, allowing the sun's rays to pass well to the back of the throat for eight to ten minutes; within this time relief from pain and discomfort is experienced. The procedure is repeated as the patient's condition demands it. The author believes that the curative effect is due to (1) attenuation of the pathogenic power of micro-organisms through strong light; (2) thermic action upon inflammation, (3) and chemic effect upon the local nutrition rendering the tissue more resistant.

Ecchymosis of Eye.—The ordinary "black eye," if seen at once, write C. A. Wood and T. A. Woodruff (Medical Standard, Jan., 1902) is best treated by cold applications (cloths wet with ice-water) or by an evaporating lotion such as the following:

℞ Liq. plumbi subacetatis.....3j
Alcohol 3j
Aq. dest. q.s. ad.....Oj

When a definite blood-clot has formed, the skin should be incised or two or three leeches applied to the orbital margin. After two days the only thing to do is to apply flesh-colored paint to hide the discoloration.

Abrin and the Digestive Ferments.—It having been shown that abrin, the active principle of jequirity-bean, acts much more feebly by mouth than by subcutaneous or intravenous injection, S. K. Dzierzgowsky and N. O. Sieber-Schoumoff (Archives des Sciences Biologiques, Vol. VIII., No. 5, 1901) instituted experiments and reached the following conclusions: Abrin can pass through porcelain filters, and its toxicity is enfeebled to a slight degree by hydrochloric acid of the strength found in gastric juice, or by the various digestive ferments. Given by mouth it is partly destroyed in the organism, and, under the influence of conditions existing in the digestive tube, not only loses its poisonous properties, but has its other powers modified. For example, an extract of the excretions containing it can no longer cause a conjunctivitis or bring about the characteristic pathological lesions.

Organic Preparations in the Treatment of Fatty Stools Occurring in Pancreatic Disease.—Serious interference with the absorption of fats unaccompanied by icterus but associated with diabetes mellitus is described somewhat rarely in medical literature. Two dozen cases have been collected by H. Salomon (Berl. klin. Woch., Jan. 20, 1902). Very few autopsies are reported in cases belonging to this class, but it is reasonable to assume the presence of pancreatic disease or of some cause which shuts off the pancreatic juice from the intestinal canal. Fles and Langdon-Down were among the first to use pancreatic substance or pancreatin in the treatment of serious cases of steatorrhea. In the first case described by Salomon the fat in the stools of a glycosuric patient was equal to about 50 per cent. of the fatty input. The steatorrhea was promptly diminished upon the administration of pancreatic substance and of pancreatin-Aachen. During the period of treatment with these preparations N—resorption increased, while the elimination of fat was diminished to less than 20 per cent. of the quantity represented in the patient's diet. Recent investigations indicate that in diabetics the acetone-bodies which appear in the urine are products of fat. In conformity with this theory Salomon found that acetone elimination was relatively large in his patients during the periods when pancreatin was being administered and when the absorption of fats was relatively good.

Electricity in the Treatment of Sprains.—The use of electric currents in cases of sprain is not so frequent as it ought to be in view of the benefits which it offers. Charrier and Planet (La Presse Méd., Jan. 8, 1902) enumerate these benefits as follows: Immediate cessation of pain results from the first treatment. Thanks to the analgesia produced, movement of the articulation becomes possible. The disappearance of the pain is, however, but temporary, necessitating renewed treatment. The electric current promotes absorption of the periarthritic exudate in cases of recent sprain. In long-standing cases, in which the functional prognosis is grave, the faradic current effects a degree of amelioration which ranks it among the most valuable of available measures. A rapidly intermitting induced current is employed. The electrodes are placed over the articulation, the negative electrode in contact with the most painful area. One or two sittings daily, of a duration of from five to ten minutes, give marked relief.

Suggestion in Medicine.—Susceptibility to suggestion is present in healthy individuals and is probably much greater in persons suffering from disease. The adult patient consulting a doctor is in a very receptive mood and a ready recipient of any suggestion a physician may make. If the patient is apprehensive, writes G. C. Smith (Boston Med. & Surg. Journal, Jan. 30, 1900), great caution is necessary in the method of examination; a pessimistic patient is more open to evil suggestions than to good ones. To secure most good from suggestive therapeutics, one should not say the remedy *may* relieve, but that it *will* relieve. Only one sugestion should be made at one sitting, as the mind is best influenced by keeping one thought dominant for several days, until the idea becomes fixed. Suggestions should be founded on facts, some of which at least can be demonstrated to the patient. The pernicious influence of evil suggestion is illustrated in cases of traumatic neurosis. Another evil result of suggestion is seen when surgeons summarily dismiss their patients immediately after operation without reference to subsequent treatment. Aches and pains return without warning; friends are consulted, the surgeon is criticized and the profession falls into disrepute. A long time may be required to rid a patient's mind of ideas jeopardizing health, which have been allowed carelessly to take root. Smith recommends thorough psychological preparation for the medical school, as a means to more exhaustive examination, keener observation and better control of patients.

Treatment of Cardiac Dilatation.—"Like dress, fashions of disease 'come in' and, after lasting a variable period, 'go out.'" Recently a remarkable popularity for appendicitis has been noted, and many have fallen victims to the operation. Enteroptosis and adenoid growths are conditions which now receive their full share of attention. Although weak and dilated hearts have undoubtedly increased relatively in numbers during the past few years, fashion has been assisted in the creation of this lesion, according to I. B. Yeo (Practitioner, Jan., 1902) by the dire influences of the grippe, excessive muscular exercise and the tobacco habit. He attributes many dilated hearts, especially in middle-aged people unused to exercise, to the unreasonable cycling habit. Many young men of rather small stature are proud to boast of their health and athletic prowess, little dreaming that their efforts to compete with men of much greater power has caused a much dilated and hypertrophied heart. He believes that the pernicious influences upon the heart occasioned by influenza may be largely avoided by a prolonged period of physical rest. He also insists that too little attention is paid in the later stages of failing compensation to this method of treatment—"rest in bed." Baths and "resisted exercises" have become too popular and

are often indiscriminately employed. He accounts for the beneficial results of saline baths and the effect which they have in decreasing cardiac dulness by the modification of the type of respiration which is occasioned. The superior costal type takes the place of the abdominal type, and there is an increase in expansion of the upper parts of both lungs. In mild cases general tonics are all that are necessary. When dyspnea and troublesome palpitation are present the following prescription is of great use:

℞ Ferri et ammon. citratis.....gr. lxxx
Tinct. digital.....m̃xl
Sprt. ammon. arom.....3ij
Infus. calumbæ, ad.....3viij

M. et sig. One ounce twice daily after meals. In less serious cases the following may be used as a good tonic:

℞ Quininæ sulph.....gr. xvj
Tinct. nucis vom.....3ij
Vel tinct. stroph.....m̃xl
Ext. cocæ fl.....3iv
Spts. chloroformi.....m̃lxxx
Aquæ, ad.....3viij

M. et sig. One ounce twice daily before meals. In anemic cases iron and nux vomica are very beneficial when followed by an aperient to keep the bowels in condition:

℞ Ferri sulph. exsic.....gr. xxxvj
Saponis.....gr. xviij
Pulv. nuc. vom.....gr. xxiv
Aloin.....gr. iv

M. et Div. in pillulas XXIV. One pill twice daily.

Lecithin in Tuberculosis.—The therapeutical application of lecithin has been studied in relation to various diseases. H. Claude (Rev. d. l. Tuberculose, Vol. VIII., No. 4, Dec., 1901) has sought to ascertain by experimental means its effect in tuberculosis. Animals were first inoculated with tuberculosis, two-thirds of the number so treated receiving lecithin by mouth or subcutaneously; the remainder received no medicament and succumbed to a general miliary tuberculosis about a month after inoculation. In those to whom lecithin had been administered, life was prolonged from one and a half to six months. In every case the body weight was preserved and in some instances it was increased; diminution and elimination of phosphates was diminished and elimination of urea increased. Necropsy showed that the disease had taken a more benign form and, instead of giving rise to a diffuse infiltration or caseation and ulceration, there was a tendency to sclerosis with limitation of the lesions. This modification of the tuberculous process, contrasted with its course in the untreated animals, would seem to be due to increased resistance given to the defensive elements of the organism through the introduction in excess of a substance already existing in the body.

Creosote in Pneumonia.—In a series of eighteen patients treated by this drug at the Roosevelt Hospital, W. H. Thomson (Med. Rec., Feb. 1, 1902) believes that many favorable results could be attributed to remedy. Only one death occurred, but as several were mild cases no deductions could be made in regard to mortality. The peculiar course of the temperature after the administration of the drug seems to denote a specific action. The disease terminated by crisis in only five days. In most of the cases there was a fall of from one to three degrees within twenty-four hours, followed by a rise and an irregular course for several days. The drug seems to act very favorably upon that important complication of pneumonia, tympanites. When given as the carbonate of creosote the stomach seems to have much greater toleration. About 180 grains are given in twenty-four hours, and no depressing effects upon the circulation have ever been noticed. Furthermore, there need be no fear of an injurious effect upon the kidneys. His usual formula is:

℞ Creosot. carbonat.....3ss
Glycerini.....3i
Aq. menthæ, ad.....Oss

M. et sig. Half an ounce in water.

SKIN AND GENITO-URINARY.

Psoriasis and Glycosuria.—The true etiology of psoriasis is still in doubt. English and American writers especially regard the disease as a dyscrasia, having possible etiological relations with rheumatism, gout and diabetes. Statistical evidence does not support the view that glycosuria and psoriasis are closely related, says W. Pick (Berl. klin. Woch., Jan. 20, 1902). Weinbrenner found diabetes to be present only once in over 500 cases of psoriasis, Schütz once in 100 cases, Nielssen once in several hundred observations. Bulkley was never able to find sugar in the urine of his numerous psoriatic patients. Pick experimented with 50 cases of psoriasis and 50 cases of various skin diseases, including eczema, scabies, prurigo, furunculosis, pityriasis rosea, urticaria, etc. To these patients 100 grams of grape-sugar was given two hours after breakfast; the urine was later tested for sugar. In 2 out of 50 psoriatics alimentary glycosuria was produced; 3 of the other 50 patients, all sufferers from widespread eczema, showed alimentary glycosuria. It appears that alimentary glycosuria is not more frequent in patients having psoriasis than in those having other chronic cutaneous diseases. It is not shown, however, whether psoriasis is to be regarded as a dyscrasia, or whether it is a neurosis, as French authors believe, or whether it is a local parasitic affection or dermatomycosis, as Neisser, Unna and others teach.

Indications and Limitations of Massage of the Prostate Gland.—The indications for massage of the prostate, as defined by L. E. Schmidt (Chicago Med. Rec., Jan. 15, 1902) are all those inflammatory diseases of the prostate gland in which it is desirable to enhance absorption, or in which the prompt and regular removal of accumulated secretion is desirable. Massage is furthermore indicated in insufficient development of the prostate and prostatic sphincter in youthful individuals and also in certain cases of sexual exhaustion. Stimulation of the circulation hastens the removal of inflammatory infarctions and congestions such as occur in simple catarrhal prostatitis. After a posterior urethritis symptoms may remain which are referred to the region around the perineum and anus. There may be no apparent urethral cause and prostatic swelling may be slight or may even be absent. Massage is obviously contraindicated if fever be present or if the prostate be exquisitely tender. In essential neuroses of the prostate great caution is necessary; under massage the prostate not only becomes exquisitely sensitive, but the general condition of the patient often changes for the worse. Massage of the prostate is done with the index finger, which is protected with rubber and well oiled to avoid unnecessary pain. In order to reach as high as possible one should avoid pushing against the coccyx and should exert pressure toward the perineum. In selected cases the use of instruments or of metal tips for the fingers may be necessary; in most cases the finger can reach all parts of the prostate and can carry out a thorough massage with greater delicacy and exactness than can be attained when instruments are used. In inflammatory cases very light rotating and stroking movements should be used; in old chronic cases, in which secretions have collected in cavities, energetic pressing movements will more effectually express such secretions.

Two or three minutes are required for each treatment, and the number of these each week depends upon the case. In persistent cases a pause of several weeks may be advisable.

SURGERY.

Surgery of Obstructive Jaundice. — Contributions from this field are perhaps more welcome than from any other in the broad domain of surgery, and one from the hand which has done most to advance knowledge in this line must be particularly welcome. A. W. Mayo-Robson (Brit. Med. Jour., Jan. 18, 1902), in reviewing his experience with 200 recent cases, illustrates with a fecundity of brilliantly massed facts that, in expert hands, it is as safe to operate for obstructive jaundice as for any common abdominal lesion. Unfortunately the paper is short and he devotes a major part of it to the diagnosis, which will always be the paramount problem in these cases. The following causes of chronic jaundice must be taken into consideration: (1) Common duct cholelithiasis; (2) chronic pancreatitis; (3) simple stricture of the common bile-duct; (4) inflammatory adhesions causing pressure on, or stenosis of, the hepatic or of the common bile-ducts; (5) hydatid disease of the liver pressng on, or discharging into, the bile-ducts; (6) gummata implicating the ducts; (7) chronic catarrh of the bile-ducts; (8) cancer of the common bile-duct; (9) cancer of the head of the pancreas; (10) cancer of the liver associated with jaundice due either to catarrh or to pressure; (11) cirrhosis of the liver; (12) other rare causes, such as aneurism of the hepatic artery or of the aorta, and other tumors of the liver, gall-bladder, pylorus, or kidney, pressing on or occluding the common bile-duct. It will be seen that surgery holds out a good prospect of cure in the first five cases enumerated; that medical treatment alone is advisable for causes 6 and 7, and that in the remainder with certain exceptions relief can be hoped for only from medical or surgical treatment. As in many other conditions, pain is the most valuable guide in establishing a differential diagnosis between these possible causes. A painless onset of chronic jaundice points to chronic catarrh due either to cancer of the liver or of the head of the pancreas, or both. On the other hand, pain in the upper abdomen, followed within twenty-four or thirty-six hours by jaundice, strongly suggests cholelithiasis. Here the jaundice is less intense and is pretty certain to be accompanied sooner or later by intermittent fever, chills and sweats, with very marked icteric fluctuations. Ascites is very suggestive of malignant disease; it points to it perhaps more strongly than any other single symptom. Other diagnostic anti-operative aids are as follows: Jaundice in cancer of the bile-ducts and head of the pancreas tends to become absolute; in almost every other condition it is variable. Fat in the feces and glycosuria, with very rapid wasting, are very suggestive of pancreatic trouble. If the anti-operative signs be difficult of true interpretation, those found after the abdomen is opened call for as much or more acumen. Adhesions in the neighborhood of a contracted gall-bladder suggest stones but this may be induced by a simple pyloric ulcer. If the head of the pancreas be swollen and harder than normal one should not too hastily pronounce it cancer; it may very probably be a simple chronic pancreatitis, curable by cholecystotomy. Again the discovery of enlarged glands does not warrant a gloomy prognosis, for discrete nodules are frequent in common-duct cholelithiasis and in chronic pancreatitis. If they are fused, however, the outlook is bad. The tumor composed of matted omentum and the viscera adjacent to an inflamed gall-bladder always presents a conundrum which aspiration even may not solve; it should not be pronounced malignant until the liver has been carefully inspected for nodules. The treatment depends on the diagnosis (1) If it be doubtful, an exploratory incision is indicated if the patient's general condition will permit. (2) If malignant disease be positively diagnosed, operation can, with some few exceptions, do but little good save when all the diseased tissue can be removed. (3) If gall-stones or any of the first five factors be diagnosed, operation is decidedly advisable if the patient be at all able to bear it. The two great dangers are hemorrhage and shock, accidents such as are liable to follow any severe abdominal shock. A study of the unsuccessful cases will no doubt reduce the mortality even lower than it already is; within the last year it has dropped in choledochotomy from 14.5 to 7.4 per cent. The anti-operative treatment of ordinary cases is in no way different from that given for a general laparotomy, but when a hemorrhagic condition is expected calcium chloride is fed in heroic doses, as this has been found to aid materially in limiting capillary hemorrhage by increasing the coagulability of the blood. An efficient aid in preventing shock is the use of a heated operating-table; another, even more important, is a decrease in the time of operating; exploration must be done in from ten to fifteen minutes, choledochotomy in a half hour; the more complicated operations should never take over one hour.

EYE, EAR, NOSE, AND THROAT.

Significance of the Tonsil.—It is almost universally believed that the faucial tonsil has a function to perform and should never be removed unless the operation is strongly indicated. F. H. Bosworth (Med. Rec., Jan. 11, 1902) has for many years held the view that the presence of a tonsil of any appreciable size means a diseased organ rather than a normal, functionating one and that there can be no ill results from its removal. The lacunæ are especially liable to harbor bacteria of all descriptions, and when the tonsil is swollen and enlarged it proves to be an excellent medium for systemic infection. In removal of the tonsils he always uses chloroform with children, but not to the surgical degree, and has never had any ill-effects. He has discarded the tonsillotome because it does not fit the tonsil and thorough extirpation is, therefore, not possible. The cold wire snare is preferable and can be more effectively used in removing a second portion. Furthermore, the danger from hemorrhage even in adults is, thus, almost entirely eliminated.

Aural Complications of Influenza.—Attention is called to the gravity of the inflammatory processes in the ear resulting from influenza by S. M. Smith (Phil. Med. Jour., Jan. 11, 1902). "Hemorrhagic otitis" has long been known as the distinguishing feature of otitic influenza. Mastoid implication is, however, present in all severe cases, a large number of which require operative interference, and meningitis, lateral sinus thrombosis, intracranial and extradural abscesses as sequellæ are encountered more frequently in each succeeding epidemic. It is well to examine the aural discharges for the presence of the bacillus of influenza. As regards treatment and prophylaxis, emphasis is laid on attending to aural complications at the very inception of the attack. Absolute rest in bed, with free diuresis, diaphoresis, catharsis and restricted diet, is followed by local measures, such as hot instillations, not necessarily medicated. Blood-letting in front of the tragus, to be effective, must be early. As soon as the membrana tympani shows any distention it should be incised. Hot irrigations should be followed by thorough drying and insufflation with aristol or nasophen.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, FEBRUARY 15, 1902.

HEREDITY AND ENVIRONMENT.

In this issue of the Medical News, we present among our original articles a very full résumé of the recent interesting investigations and opinions with regard to the important subject of heredity. One really striking advance in our knowledge of this subject is the very different appreciation of the great influence of the ovum in heredity as compared with that of the spermatozoon. At the end of the eighteenth century and even at the beginning of the nineteenth, it was the custom to think that the spermatozoon was the most important generative element for the development of the new human being. The *homunculus* of which Sterne has so much to say in Tristam Shandy, the original germ particle which was to receive only its nourishment from the ovum, was supposed to be the preformed embryo as it issued from the male testicle. It was not too much to expect then, as was the habit in that day, that the father was the dominant influence in matters of heredity. Now almost exactly the opposite theory holds and the influence of the ovum is considered the prevailing factor.

This change of opinion is partly due to the fact that the significance of environment for the growing organism is better realized than was formerly the case. After all from the first moment of independent existence the germ of the new being is submitted to the environmental influences concomitant with its drawing its nourishment from the maternal tissues. Perhaps there is on the whole in our day a tendency to exaggerate the influence of maternal factors on the development of the organism and especially to demand too large a rôle for the ovum as the basic germ-particle, relegating the spermatozoon to the function of merely supplying vital stimulation. It must be remembered that the birth of twins is distinctly a family trait that can sometimes be traced for generations without a break. Multiple births used to be attributed almost entirely to the influence of the ovum and to certain inherent family tendencies. Statistics, however, show that, while multiple births recur in families, they follow the male side of a family as well as the female. It has often been noted that where twins have appeared in a first marriage, they also are prone to occur in a second marriage of the husband as well as of the wife. These facts would seem to indicate for the spermatozoon more actively developmental qualities than are sometimes allowed at present.

Beyond the sphere of the mechanism of inheritance comes the interesting question of the matter of heredity—what can be inherited? While most medical men seem to think that inheritance involves the direct transmission of qualities from parent to offspring, there is at present no scientist who would willingly concede the direct inheritance of acquired qualities. It is not unusual to hear it said that a heart lesion in a patient is not surprising as the family history shows that one of the parents had a similar lesion. Almost needless to say there is no such hereditary transference as this. Early degeneration of the kidneys is sometimes explained on the ground that a parent was suffering from chronic kidney disease at the time of conception. This is of course quite as inadmissible an example of *post hoc ergo propter hoc* as the former case. What may be transmitted in such case is not the pathological lesion itself, but a weakened habit of body that leaves the organism liable to disease early in life and that may well cause the descendant organism to be affected not unlike the parent if it has to go through stresses and strains in life. This phase of heredity Dr. Kiernan has discussed very fully in the article already referred to and very little if anything can be added to the conclusions he leads up to so lucidly.

The question of sexual heredity, because it involves the future of the race from its close con-

nection with the reproductive instinct and because it represents one of the most intricate problems in heredity, must continue to attract unfailing attention. Gradually the realization has been gaining ground that human beings are differentiated into sexes not alone by their sexual organs, but almost by every cell in their bodies. What is to all intents and purposes as far as sexual organs go, a man, may still possess many of the characteristics of the woman. There may even be the physical peculiarities of a distinct feminine waist line and womanly breasts with the other organs those of the male. Not infrequently Nature does not seem to quite make up her mind as to whether an individual is to be male or female. In this case it is not surprising to find in the male with certain easily recognizable female peculiarities of voice and gesture and posture and ways a tendency to homosexuality that shows how deep are the wellsprings of these seemingly superficial characteristics. Many of the unfortunate sexual perverts and inverts are of this class. They are much more to be pitied than to be blamed and this aspect of the question deserves the careful consideration of all well meaning men who are brought in contact with unfortunate creatures.

There are many things in the body of scientific observations that are gathering around the problems of heredity that are worthy of the attention even of the busy practitioner. Obscure questions in pathological development are illumined not a little by recent discoveries. We have gotten away from heredity as a cast-iron predisposition to certain definite results. As Dr. Kiernan says, "Heredity is an initial velocity," but many modifying forces are at work and life is the resultant of all the forces. "Heredity is a prophecy of what *may* be, not a destiny which *must* be." There are always in the subject's own hand, and especially in those of the guardians of the very early years, possibilities of guidance in development that may offset or greatly aid hereditary influences. This is especially true of the intrauterine life. In a word, we are not the creatures of mere circumstance, but the resultants of many factors that may under favorable conditions always be made to bring out the tendency to true evolution rather than degeneration.

HEPATOPANCREATIC CHOLECANATOMY.

It is impossible to appreciate the pathology of acute hemorrhagic pancreatitis, or, indeed, of almost any lesion in the hepatopancreatic region, without a clear mind picture of the anatomy of the parts. That these are multitudinous may be gathered from noting the review on a near page of Mayo-Robson's recent article on the "Surgical Treatment of Obstructive Jaundice," in which he endeavors to differentiate this condition from a dozen close-of-kin disorders. Also from a study of the recently-published work of Hans Kehr. His classification can very profitably be compared with that of Mayo-Robson. It is as follows: (1) Stone in healthy gall-bladder, cystic duct free. (2) Stone in a previously inflamed gall-bladder, ducts free, adhesions. (3) Subacute cholecystitis without stone, adhesions. (4) Acute cholecystitis with stone. (5) Acute cholecystitis in contracted gall-bladder, ducts closed. (6) Hydrops of gall-bladder. (7) Empyema of gall-bladder, stone in cystic duct. (8) Carcinoma of gall-bladder. (9) Stone in common duct, acute obstruction. (10) Stone in upper segment of common duct, chronic obstruction. (11) Stone in common duct near papilla. (12) Obstruction of common duct from pressure of tumor on other organs.

It will thus be seen that the disorders of these parts are as manifold as they are confusing. In a previous editorial it is stated that a frequent cause of pancreatic disorder is the abnormal flow of bile into that organ. Turning to the classic anatomy of the liver ducts we find them described as the hepatic, the cystic and the common. Two main trunks of nearly equal size issue from the liver at the transverse fissure and unite to form the hepatic duct, an inch and a half long, between the layers of the lesser omentum, where the cystic duct joins it at an acute angle to form the common duct. The cystic, the smallest of the three, is an inch and a half long. Its mucous membrane is thrown into a series of crescentic folds, from five to twelve in number; they form a sort of spiral valve. The common duct, the largest, is three inches long, has the diameter of a goose-quill, and is formed by the junction of the two smaller ducts. It descends behind the first part of the duodenum in front of the portal vein; to the right of the hepatic artery, it then runs for a short distance along the right side of the pancreatic duct and passes with it obliquely between the mucous and muscular coats. The two ducts open by a common orifice on the summit of a papilla (papilla of Vater) at the inner side and just below the middle of the descending duodenum.

The pancreatic duct, called the canal of Wirsung, begins near the tail of the organ, runs obliquely downward from left to right, receives

the ducts of the lobules and falls into relation with the common bile-duct. There is occasionally a small accessory pancreatic duct (the duct of Santorini).

Such is a general outline given by text-books. But in this region, as elsewhere, the anatomy is typal rather than typical. Dr. Geo. E. Brewer states that, while the position of the cystic and common ducts is fairly constant, much variation is to be found in the length of each; the cystic may vary from ½ to 2½ inches; the common, from 1½ to 4¾ inches. The duodenal orifice of the common duct averages 12 millimeters. The cystic duct, owing to the spiral valve of mucous membrane, rarely permits the passage of a probe; this is not true of the remaining ducts.

Dr. Brewer has shown that we must look to embryology to explain the existence of a direct canal from pancreas to liver. Early in fetal life a bud projects back into the posterior mesentery; from this the two pancreatic ducts develop. It is usually taught that the smaller Santorini is closed in 90 per cent. of all cases. In truth, however, it is *patent* in about this number. Although this duct usually opens directly into the duodenum, its mouth is frequently found in the common bile-duct. Any obstruction distal to this entrance would force bile into the pancreas. Another interesting path for the bile to this organ is described by E. L. Opie of Baltimore. For a variable distance in the gut-wall the two ducts are separated only by a diaphanous membrane. The cloacoduodenal orifice is much smaller than the opening of either duct, so it is the most frequent lodging-point for stones. The symptoms depend entirely on the size of the stone; a large one blocks all three openings and jaundice results; a small stone stops only the cloacoduodenal ostium and gives rise to the vague chain of symptoms by which we may or may not recognize pancreatitis.

"GRATTEZ UN AMERICAIN ET VOUS TROUVEREZ UN ANGLAIS!"

It should give the American profession a feeling of self-satisfaction to hear from others words of praise, particularly when they come from the supposedly uncharitable lips of an Englishman. It fills us with wonder that a stranger in a few days' observation could learn more interesting details of our customs, of our institutions, of our manners, good and bad, than we ourselves acquire in a lifetime. Best of all, it thrills us with genuine delight that there should be to-day such spontaneous good fellowship and harmony between British and American physicians as the quaint words above indicate.

The leading article in the *British Medical Journal* for January 25th by Dr. G. B. Ferguson, President of the British Medical Association, entitled "Notes on Some American Hospitals," affords us an interesting vista of ourselves as others see us. Any one who believes that British estimate of our virtues is below par should read this charming and delightfully naïve contribution. Dr. Ferguson is whole-heartedly generous, giving us oftentimes more credit than we may merit, but when he says that the Americans are always pleased to have commendation from a surgeon of the old mother country he speaks truly. There are some passages which are delightfully unique, reminding one of paragraphs from Humbolt's descriptions of aboriginal people. "They dress in canvas boots, linen trousers and coat, all sterilized, and wear a night-cap and long sterilized India rubber gloves. Commonly they take baths before an operation and shower baths after. They make their own laws regarding divorce, for instance; they may, as in the State of Maine, exclude alcoholic beverages. Marriage with the deceased wife's sister is legal —and the States may and do make the most diverse laws regarding medical matters and regulations of health. In New York you are reminded that the fine for spitting in the cars is £100."

In describing the operations seen, the author says, "The temperature was frequently 85° F. and it was necessary for one of the nurses to wipe all the faces at short intervals with a swab; this was done in a friendly way and commonly elicited smiles from both persons. * * * The nurses are treated with much deference and are not called 'nurse.' 'Miss C——, may I trouble you for another ligature?' was the mode in which they were addressed."

"The great characteristic of American hospitals is the worship of asepsis, which I have never seen so consistently and completely carried out anywhere else." His comment on drug dispensing is pleasing. "I was surprised to see how few and simple the drugs and mixtures were. There is none of the radiant polypharmacy which is indeed much more in evidence in Britain than in America. The simplicity and directness of the prescriptions told of strength and knowledge." Some therapeutic gems are as follows: "The bath was the great treatment in typhoid and I was told that any one who would withhold se-

rum might expect an early summons before the magistrate. When I expected much, I received nothing. American ingenuity is tired of splints and is working in the directness of asepsis and ingenious suturing. * * * At the Johns Hopkins, the greatest novelty to me was silver foil for the dressing next the skin. I have brought back with me some of their gloves and this foil and also hemostatic forceps (Halsted's mosquito) for my collegues to make trial of."

Dr. Ferguson was particularly happy over the mode of life of the nurses at the Presbyterian Hospital. "The whole flat roof is used as a 'solarium,' and hammocks, seats and couches were all about. After seven P. M. the roofs belong to the nurses, they play games there and no male person is allowed to be there or even look on. I asked one of the surgeons what they did; he said he did not know, but they enjoyed it very much. * * * The sum of my observations showed me that the Americans are careful and painstaking, rather than quick and showy surgeons. They make more use than most of scissors, both for separating and dividing, and they are really the premier aseptists of the world. They scout the idea of having learnt aseptic principles from the Germans and unanimously give the whole credit of their present arrangements and of their surprising perfection to one man only and to one pioneer hospital alone and the date was five or six years ago and the man's name is McBurney and that hospital is the Roosevelt. * * * My advice to others is to do as I did. A visit to America is in many ways a great eye-opener. Nowhere else have I looked on such a scene as New York by night. See the Americans at home and you will see some of the cleverest men and handsomest women in the world. Be just and friendly and cordial with the men of America and you will find that they are only waiting for an excuse to extend the hand of true and lasting friendship. 'Grattez un Russe,' said Napoleon very rudely, 'et vous trouverez un Tartare!' 'Grattez un Americain,' say I, 'et vous trouverez un Anglais!'"

ECHOES AND NEWS.

NEW YORK.

Hospitals in New York.—A correspondent of the *New York Times* calls attention to the unequal distribution of hospitals on Manhattan Island. He writes: "The Nineteenth Ward of the Borough of Manhattan, it seems, is to have another hospital and dispensary added to its already large number of similar institutions. The Manhattan Maternity Hospital and Dispensary is to be located on the plot of ground made up of 327, 329, 331, and 333 East Sixtieth Street. Of late years this section of our city has become veritably the Mecca of benevolent enterprises in this line, for reasons not easy to explain unless for the convenience of those who foster them. They are also aggregated within comparatively a small area—one bounded only by Fortieth and Eighty-third Streets, Fifth Avenue, and the East River. In this space there are seventeen; all but two have outdoor departments, and three have maternity departments."

All Hospital Patients Vaccinated on Admission.—Dr. Brannan, President of the Board of Trustees of Bellevue and Allied Hospitals, sent to Bellevue last week an order to the effect that all patients received at Bellevue and the allied hospitals should be vaccinated on their admission to the institutions, except cases in which the condition of the patients was very weak.

Milk Producers for Reform.—The Directors of the Five States Milk Producers' organization, in regular session, held at Binghamton, N. Y., February 7th, again declared their willingness to coöperate in all efforts to prevent impure or unfit milk being sold in New York City. They arraigned the present method of the distribution of milk from producer to consumer as responsible for most of the evils complained of, as unbusinesslike and wasteful; as making reform difficult, if not impossible, and as intolerable to both producer and consumer; and invited correspondence and cooperation with health officers and all other parties interested in furnishing pure, whole milk to consumers in New York City.

The Reunion of the New York Profession.—At the recent meeting of the Medical Society of the State of New York, the retiring President, H. L. Elsner, M D., was made Chairman of a Committee of five to confer with a committee of equal number representing the New York State Medical Association for the purpose of formulating a plan by which the regular profession of the State of New York might be united. Dr. Elsner has selected as his associates on this Committee Dr. Abraham Jacobi of New York, Dr. Albert Vander Veer of Albany, Dr. A. M. Phelps of New York and Dr. George Ryerson Fowler of Brooklyn.

Classification of Pulmonary Tuberculosis.—The following preamble and resolutions were adopted by the New York Academy of Medicine at its meeting held February 6th, and copies were sent by instruction to the Treasury Department, to the Surgeon-General of the Marine Hospital Service and to the Secretary of the New York State Medical Society:

Whereas, The Treasury Department of the United States, upon recommendation of the Surgeon-General of the Marine Hospital Service, has recently decided to classify pulmonary tuberculosis with dangerous contagious diseases, be it

Resolved, That the New York Academy of Medicine deeply deplores this decision, which is not based either on clinical experience or on scientific experiments.

Resolved, That the Academy considers the exclusion of non-pauper tuberculous immigrants and consumptive aliens visiting our shores, unwise, inhumane, and contrary to the dictates of justice. Be it further

Resolved, That, while the Academy is convinced of the communicability of tuberculosis and urges all possible precautions against the spread of the disease occasioned by sputum and tuberculous food, the Academy is opposed to all measures by which needless hardship is imposed upon the consumptive individual, his family, and his physician.

Woman's Hospital. The Governors of the Woman's Hospital recently sold their old site at Lexington Avenue and Fiftieth Street to the New York

Central Railroad for $400,000. They have now purchased a new location for the Hospital on 109th Street east of Amsterdam Avenue.

Policemen Vaccinated.—On Thursday of this week, by order of Police Commissioner Partridge, all the policemen of Greater New York reported to their respective station-houses and were vaccinated.

PHILADELPHIA.

Contagious Diseases Increase.—During the week ending February 8th there were reported 254 new cases of typhoid fever and 110 cases of smallpox. This is an increase of 53 cases of typhoid and 37 of smallpox over those of the previous week. Compulsory vaccination is still being carried on in many of the lodging-houses of the city. Dr. John V. Shoemaker, President of the Department of Charities and Correction, has recommended to the Department of Public Safety the discontinuance of quarantine for smallpox. He says in part: "In places from which a case of smallpox has been removed I consider sunshine, fumigation, and plenty of fresh air much more effectual as remedies than the close and continuous quarantining of houses. Shutting people up in the house in the minds of many experts is liable to increase rather than decrease the scope of an epidemic." Regarding the report on February 3d of the committee appointed by the Director of Public Safety to determine if proper means were being employed to stamp out smallpox, Dr. Shoemaker, Chairman, says: "Our report stating that the Municipal Hospital is equipped with all approved means of caring for smallpox, that a corps of competent physicians is in attendance and that the patients are well quarantined is founded on personal observation and investigation made by members of the committee." The committee, which includes Drs. Shoemaker, Tyson, Hare, Anders and Henry, also states that the seriousness of the epidemic was not such as to alarm the residents of the city and that adequate precautions in the way of house-to-house vaccination, isolation, quarantine, disinfection, etc., are being taken. Vaccination is again urged as the only thorough remedy.

Druggists to Combine Against "Cut-rate" Stores.—A combination of the independent retail drug-stores of the city is being formed with a capital of $1,000,000. It is the purpose of the trust to acquire all the well-established independent stores, retaining the proprietors as managers at a guaranteed salary and commission, and so fight the larger "cut-rate" establishments. It is reported that more than 100 druggists have already joined the combination.

Domestic Animals Slaughtered to Prevent Spread of Smallpox.—A despatch from Wilkesbarre states that 2,000 dogs and cats are to be killed in Plymouth township. More than 40 cases of smallpox are now being cared for and the Board of Health has decided that the large number of cats and dogs are spreading the disease.

Poem by Dr. Weir Mitchell.—At the celebration of Washington's Birthday by the University of Pennsylvania, Dr. S. Weir Mitchell will read a poem.

Hatfield Prize for 1903.—The Nathan Lewis Hatfield Prize of $500 is to be awarded by the College of Physicians of Philadelphia to the author of the best essay on "The Relation between Chronic Suppurative Processes and Forms of Anemia." Competition is open to members of the medical profession and men of science in the United States. Particulars may be obtained from the Chairman, Dr. J. C. Wilson, College of Physicians, Philadelphia.

Dr. Welch for President of Society.—It is announced that the Philadelphia County Medical Society will present as its candidate for the presidency of the Medical Society of the State of Pennsylvania, Dr. William M. Welch, the well-known authority on contagious diseases.

College of Physicians.—At the meeting of February 5th Dr. D. L. Edsall reported "A Remarkable Case of Coma apparently due to Acid Intoxication *sui generis*." Dr. Edsall prefaced his remarks by a discussion of the various phases of acid intoxication and the accompanying conditions. In one group of cases acetonuria is the only manifestation. In a second group acetonuria is accompanied by diaceturia and perhaps oxybutyric acid. Gastro-intestinal disturbances accompany each but are not marked. There may also be slight urinary evidences of acid intoxication. In a third group there is marked urinary evidence of acid intoxication. The case reported was that of a man previously healthy who was rather suddenly seized with vertigo which was followed by coma. That condition lasted for eleven hours, there being present the symptoms and urinary signs of acid intoxication. Paralysis was not present. A notable feature was the very marked odor of acetone about the patient. Treatment was the intravenous injection of three pints of a two-and-one-half-per-cent. solution of sodium bicarbonate, this being repeated once. Apoplexy, uremia, alcoholism, and diabetic coma were each ruled out as the cause of the coma and the case diagnosed as one of acid intoxication *sui generis*.

Adiposis Dolorosa in a Male.—Dr. F. X. Dercum exhibited this patient, stating that he was the fourth male of the entire 25 cases of the disease reported. Fifteen years ago the man suffered from a febrile attack and soon afterward began to take on deposits of fat. The back, arms and legs and later the sides and abdomen were involved. The fatty areas are very painful to pressure, are easily bruised and ecchymotic areas spontaneously appear. Epilepsy has also appeared as a complication of the case. Dr. Dercum spoke of the pathological findings in one case coming to autopsy. There was found a neuritis, disease of the thyroid gland, and sclerosis of the columns of Goll. Dr. Dercum also exhibited a second patient, a female, in whom the disease was of very slow progress. An examination of the eye-grounds by Dr. de Schweinitz revealed no changes except a circinate retinitis which he states to be in no sense a symptom of any one disease.

A Recent Research on Snake Poisons.—Drs. S. Weir Mitchell and Simon Flexner read papers on this subject, Dr. Mitchell having suggested the experiments and Dr. Flexner conducting them. While not yet completed Dr. Flexner was able to outline some results determined thus far. The research was conducted with a view to interpreting the blood phenomena caused by venoms. Dr. Flexner first gave a brief explanation of the principles of bacteriolysis and hemolysis in general and then detailed the results of their experiments to determine the hemolytic properties of venom. It was found that venous hemolysis takes place to a varying degree as the blood of different animals is susceptible to venom in a varying degree. Venom acts in a maximum way upon one kind of corpuscles. The general conclusions reached were as follows: (1) Venom is a very complex compound and contains a large number of intermediate bodies but no complement. (2) If venom contains a nerve poison, that substance unites chemically with nerve-cells to produce its effect. (3) The rapid decomposition of bodies dead from venom poisoning is due to the action of the venom upon the blood. The serum complement of the blood is fixed by the venom and as a consequence the bacteritic quality is lost. The bacteria thus rapidly multiplying when not inhibited by the serum cause hasty decomposition.

(4) Experiments with antivenin showed it to be a physiological and a chemical antidote to venom.

Brain Tumor Localized by the Roentgen Rays.—An exceedingly interesting communication was that of Drs. Charles K. Mills and G. E. Pfahler. It included the report of a case of brain tumor localized clinically and by the Roentgen rays. The clinical diagnosis of a subcortical tumor mainly in the parietal region and extending to the internal capsule was made. Dr. Pfahler, Assistant Chief Resident Physician at the Philadelphia Hospital, then made skiagraphs of the patient and obtained a shadow which exactly confirmed the clinical localization of the tumor. Operation was followed shortly by death. Autopsy revealed a large fibrosarcoma in the aforementioned location, only a portion of the tumor having been removed at the time of operation. Experiments upon cadavers were then made by Dr. Pfahler, the results being extremely gratifying. Tumors of various sorts were placed within fresh brain substance or brain that had been hardened and after closing the skull skiagraphs were made. The conclusions reached after several series of experiments were as follows: (1) Fibrosarcomata and perhaps other tumors can be photographed in the living subject and their location shown. (2) Other varieties of tumors can be photographed in their most usual locations. (3) Other abnormalities in brain tissue itself can be photographed. This may in certain cases be of value in diagnosing cysts, hemorrhages, etc. (4) The most careful technic and regard for the special conditions in each case must be observed. (5) Shadows obtained in normal portions of the brains studied show that the utmost care in interpreting any shadow obtained is necessary.

Obituary.—Dr. Adam Trau, for many years on the medical staff of the German Hospital, died in that institution February 7th of paralysis. Dr. Trau was born in Germany sixty-two years ago, graduated at the University of Pennsylvania, and, after serving as naval surgeon during the Civil War, practised in this city.

Dr. W. Murray Weidman, of Reading, died of angina pectoris February 7th at the age of sixty-five. Dr. Weidman was the local representative of the State Board of Health, was prominent in local and State medical societies, and was one of the best known physicians in eastern Pennsylvania.

CHICAGO.

Health of Evanston.—According to the health report submitted a few days ago to the Council, Evanston has been healthier during the last year than for any year since 1896. There have been 174 deaths, which, in a population of nearly 20,000, means an average death-rate of 8.65 per thousand. The largest number of deaths was among infants under one year old, and the next among persons between twenty and thirty years of age. There were three deaths of persons over ninety. Tuberculosis had the most victims, with heart disease and pneumonia next. The use of lake water is held largely responsible for the prevalence of typhoid fever. Dr. W. R. Parkes, the Health Officer, discourages the use of artesian water, as the jugs are filled and refilled without thorough washing. As it is impossible to tell from day to day just what the condition of the lake water is, he concludes that absolute safety lies only in boiling the water.

Cook County Hospital Staff.—New officers were elected by members of the attending staff of the Cook County Hospital at its regular annual meeting recently held. Information that an attempt might be made to effect a new interpretation of the rules and allow the old officers to hold over until next year brought about a large attendance. The following officers were nominated and elected: President, Dr. Arthur R. Edwards; Secretary, Dr. L. Blake Baldwin. Dr. Edwards has been on the professional force at the institution for twelve years. He is professor of principles and practice of medicine and clinical medicine in the Northwestern University Medical School. He succeeds Dr. Denslow Lewis. The Executive Committee will be appointed later and it is expected that new rules will be considered and passed regulating the management of the physicians and internes.

New Hospital.—Preparations are being made for the erection of a hospital for the Swedish Mission Association in Lake View. It is said that the hospital will cost about $50,000 when completed.

Coeducation Discussed at Rush Medical College.—The matter of coeducaton was discussed by members of the faculty at a recent meeting in a very vigorous manner and, notwithstanding the opposition of certain members to coeducation, a resolution was adopted recommending the admission of women to all branches of the medical department of the University of Chicago.

High Retraction Ring as a Contraindication to Version.—Dr. Rudolph W. Holmes read a paper on this subject before the Chicago Medical Society, February 5, 1902. He said that the retraction ring as a product of normal and abnormal labor is not given a proper recognition in American text-books; it is considered so unimportant that hardly a paragraph is given to the discussion of the ring, threatened rupture, etc., and its contraindication to version. The reports of two cases are given, occurring in a European clinic, in which version was done with a high retraction ring at the umbilicus; in one case death resulted from rupture of the uterus; the other patient fortunately escaped.

Anatomy of the Retraction Ring.—In the nonpuerperal uterus, and probably up to the moment of labor, the division of the uterus into body and cervix obtains. In labor, however, such is not tenable—here the upper and lower uterine segments are the divisions of the uterus, the former being made up of a part of the uterine body, the latter made up of cervix and that part of the body between the os internum and the retraction ring plus the cervix. Three anatomic factors in late pregnancy may often denote the potential (proximate) site of the future ring—the vein of Bayer, the "line of firm peritoneal adhesion," *i.e.*, the peritoneum of the uterovesical fold passes onto the uterus near the os internum, is loosely attached to the lower uterine segment, and becomes closely adherent near the future site of the ring, and the densely woven structure of the muscle of the upper segment and laminated structure of the lower segment with a considerable excess of connective tissue. The muscular arrangement of the two segments is more evident in advanced labor, and the segments are separated by a distinct rim or ledge—the retraction ring.

Diagnosis of the High Ring.—In every normal labor one should attempt to find the retraction ring. With a slight rise in normal labor it may be difficult or impossible to discover it; but the more one looks for the ring late in normal labor the more likely will he be to find it under physiological conditions and the more positively he will make it out in pathological circumstances. When some obstruction exists the ring will be two or more inches above the pubes—the higher it rises the more will these symptoms be present. First, increased sensitiveness of the lower segment, gradually becoming more marked until actual pain is present in contraction and also in intervals of uterine activity; palpation will bring out this pain. The round ligaments will be large, tender, and much stretched. The ring will be felt as a distinct groove running obliquely across the uterus (abdomen)—as the ring rises in spare women it may be clearly seen. The fetus may be more

clearly outlined in the interval of contractions through the much attenuated lower segment. Examining internally we may find the thin segment bounded at its upper border by a distinct ledge. With these findings, the pulse will be more frequent, temperature raised, and in extreme cases we may have the woman complaining of the impending evil. In a goodly proportion of cases the membranes will have been ruptured for some time. The ring must be differentiated from a full bladder, the success formed by the depressions of the neck being filled by uterine constrictions, lower border of the placenta, and large fibroids of the anterior wall, and in certain cases of twin pregnancies. Each of these will be excluded by a careful consideration of the characteristics peculiar to the several conditions.

Mechanics of the Retraction Ring.—At the beginning of labor the potential site of the ring is behind the pubes. As labor progresses the upper segment contracts and retracts; the lower segment dilates and stretches. In the course of normal labor retraction occurs in almost the same ratio as the child is expelled from the uterus, so the lower segment is only slightly stretched—that is, the ring mounts usually not more than two inches. In obstructed labor retraction of the upper segment goes on more rapidly than expulsion, or expulsion may be impossible from insuperable obstruction; here, as retraction of the upper segment diminishes that part of the uterine cavity as made up by it, there must be a compensatory stretching of the lower segment to give the fetus a uterine covering; this thinning permits the ring to mount to the umbilicus or even above it, the higher the rise of the ring, the more imminent is rupture of the uterus.

Therapeutic Considerations.—With a certain dogmatism one may state that the higher the ring rises with the resultant thinning of the lower segment, the more strictly must one draw one's lines against performing version. Mere elevation of the ring alone cannot be solely one's criterion—one must consider the general condition of the uterus at the moment of the tentative attempt. A high ring with intact membranes at the moment of operation will offer better results than a lower ring with membranes ruptured for a protracted period. When in doubt of the advisability of performing version prepare for the operation, pass the hand into the lower segment—if the fetus is tightly grasped by the uterus, if the segment is very thin, and the ring high, alter the plans and try tentatively the axis traction forceps. If they fail after ten tractions remove the instrument and perform craniotomy. If the child be dead perform craniotomy as the operation of election. Do not perform version on a dead baby long after the membranes are ruptured. In transverse cases perform decapitation or embryotomy as the case indicates. Decide each case on its merits and give the mother the most certain procedure; the baby is usually dying or dead so should have little consideration beside the welfare of the mother.

Exophthalmic Goiter.—Dr. Edward F. Wells read a paper with this title. After alluding to the interesting history of the affection, he spoke of the causation. The essential cause was unknown, but the symptoms are clearly due to an excessive or perverted action of the thyroid gland, a true hyperthyroidism. This seems conclusively proven from the facts, that there are evidences of excessive activity of the thyroid gland, and that similar symptoms may be and often have been produced by excessive thyroid feeding; and also because myxedema, which is the exact opposite pathologically and symptomatically of exophthalmic goiter, is clearly due to a thyroid insufficiency and is relieved by the proper exhibition of thyroid extract. The symptomatology of exophthalmic goiter in typical cases is clearly cut and pathognomonic and even in atypical cases is sufficiently distinctive to almost always allow of a correct diagnosis. The prognosis varies remarkably in the different cases. Death occurs in about 12 per cent. of the cases, but this mortality appears almost exclusively in those cases which have a rapid development of severe symptoms, especially acute nervous and mental symptoms. The ordinary case does not usually die from the effect of the disease, but the course is prolonged usually for many years, and is marked by relapses and recovery is not perfect, that is, more or less nervousness and thyroid enlargement remain permanent. Thyroid atrophy, with consequent myxedema, is a sequel in some few cases. After mentioning the ordinary measures of régime, diet, etc., attention was called particularly to a few therapeutic measures, each of which produces a definite effect and which has appeared useful in the treatment of this disease, according to the experience and observation of the speaker. Of these codein was placed at the head of the list. This agent may be given in doses ranging from one-quarter to one grain, three or four times a day and continued for many weeks or months, preferably with occasional intermissions for a few days. Codein is a most useful agent in relieving the nervous and mental excitement which is usually present, but it appears to have an effect beyond this, inasmuch as its use is usually followed by gradual slowing of the pulse and improvement in the gastro-intestinal symptoms. Adrenalin hydrochlorate, in the standard solution of 1-1000, may be prescribed in doses of from five to ten drops three times a day, and this will be followed by an evident toning up of the paretic capillaries. Digitalis or strophanthus may also be used. The removal of a portion of the enlarged thyroid, or ligation of the thyroid arteries, is the only therapeutic measure which approaches the disease directly. Partial thyroidectomy is a dangerous operation and is often followed unexpectedly by death in a few hours or days. It should therefore be reserved for the most rebellious or severe cases in which these extraordinary risks may be assumed in the presence of extraordinary dangers.

CANADA.

Winnipeg Vital Statistics.—During the month of January there were registered in Winnipeg 97 births, 55 males and 42 females; deaths, males 30 and females 13; marriages 54.

Donation of Books to the Ontario Medical Library.—Dr. Howard A. Kelly has made a handsome donation of books selected by Dr. N. A. Powell, curator of the O. M. L. A., from the books of the late Dr. Sweetman. It is understood that the cost of these was in the neighborhood of $1,200.

Toronto Nursing-at-Home Mission.—During the past year this institution has looked after 841 patients and the nurses have made 5,406 visits. The receipts for 1901 amounted to $1,365.79 and the disbursements were $1,241.69. The sum of $1,189.20 has already been subscribed toward the building fund of a new home.

Smallpox in the Province of Quebec.—Dr. Elzear Pelletier, Secretary of the Provincial Board of Health, has handed out a statement showing that during the year 1901 there were 5,069 cases of smallpox in that Province. The cases occurred in 276 localities in 55 out of 73 counties in the Province. The percentage of deaths, however, was very small, being about one per cent. Three hundred and twenty-four municipalities have reported to the Board that they have adopted the vaccination by-law recommended to them by the Board of Health.

New Hospital Opened.—The Chipman Memorial Hospital was opened at St. Stephen's, New Brunswick, on the afternoon of February 4th by the Hon. L. J.

Tweedie, Premier of the Province. The hospital is finely situated on the banks of the St. Croix River just below the town and was formerly the Chipman homestead. The building and grounds, fully equipped with all modern appliances, has been donated to the town by Lady Tilley and other heirs of the Chipman estate. It has accommodation for twenty patients and on the day it was opened the men of St. Stephen's made it a contribution of $1,000.

Toronto Hospitals Crowded.—St. Michael's Hospital, Toronto, and the General Hospital, same city, are full to overflowing, the former being so congested that the corridors have been pressed into service and for the present no new admissions are being made. There are at present in the Toronto General Hospital 325 patients, the greatest number in residence at one time in its history. This hospital has the greatest number of beds of any hospital in Canada, having accommodation for 400. The large majority of the cases are surgical and operative, the medical wards being far from full. Grace Hospital has just completed one of the finest operating theaters on the continent at a cost of $10,000, the gift of Lieutenant-Colonel Pellatt.

Protestant Hospital for Insane, Quebec.—The annual meeting of the Board of Governors of this institution was held last week, when the superintendent, Dr. Burgess, made an important proposal to the effect that he be allowed in future to accept any applications for voluntary admission to the hospital that might be made to him, without conforming to the Government requirements regarding admission to the institution. This would make the institution a hospital in every sense of the word. The annual report contained the following statistics: In residence, January 1, 1901, 192 men and 176 women, total, 368. Admitted during the year, 86 men and 64 women. Discharged as recovered, 25 men and 20 women; discharged as improved, 8 men and 8 women; discharged as unimproved, 3 men and 6 women. Died during the year 24 men and 11 women. Remaining in residence at the close of the year, 217 men and 194 women, total, 411.

Proposed Consulting Board of Health in Montreal.—Owing to the fact that the Hygienic Committee of Montreal is generally made up each year of members of the City Council who are not conversant with health matters, Alderman Ames, who has always taken a deep interest in the health of the city, proposes a consulting board to consist of four of the city physicians and a practical plumber. It is thought that in this way something could be done to curtail the three thousand odd unnecessary funerals taking place in Canada's great commercial metropolis each year.

Doctors will Decide an Interesting Legal Point.—A medicolegal case of interest is before the courts in Montreal. A clergyman recently died in that city leaving an estate of $95,000, which he had inherited from his first wife. Shortly after his demise, his widow gave birth to a child, a son, who died about six hours after his birth. The little child had been baptized before its death, but it is on its viability that the case hinges. If he was born viable, he became his father's heir. The other heirs of the estate claim that the child was not born viable and the medical testimony is awaited with considerable interest.

The Tuberculin Test.—At the annual meeting of the Shorthorn Breeders' Association, held in Toronto on the 4th inst., the following report of a special committee was adopted: "We, the members of the Dominion Shorthorn Breeders' Association, at our annual meeting, resolve that the tuberculin test is unreliable, unnecessary, and in many cases injurious, and that we urge the discontinuance of the compulsory use of tuberculin by the Dominion Government Department of Agriculture; and we also fail to see the object now of ninety days' quarantine, as there is no contagious disease in Great Britain requiring its enforcement for such a length of time."

Annual Meeting of the American Medico-Psychological Association at Montreal.—This Association will hold its annual meeting, the fifty-eighth, in Montreal on June 17th, 18th, 19th and 20th; the Windsor Hotel will be the headquarters of the Association. The annual address will be delivered by Dr. Wyatt Johnston of McGill University, the subject will be "The Medico-legal Appreciation of Trauma in Its Relations to Abnormal Mental Conditions." Amongst other Canadians who will contribute papers are Dr. Daniel Clark of the Toronto Asylum, Dr. Russell of the Hamilton Asylum and Dr. R. M. Bucke of the London Asylum.

GENERAL.

Eddyism and the Kaiser.—The last addition to the 476 varieties of quackery said to thrive in Berlin is Christian Science. It is the sensation of the moment. The comic papers caricature it, the weighty religious periodicals marshal polemics against it, and the daily press prints much descriptive matter regarding what is called "the latest American importation," saying it was only brought over after it had been "worn out in the United States." The German followers of the American Christian Science community in Berlin number about 200 persons. Emperor William is so incensed at the Spiritualist movement that he has issued a notification, through the "North German Gazette," that all persons in any way connected with Spiritualists, faith healers, Christian Scientists, or kindred cults will hereafter be rigidly excluded from the imperial Court. The Emperor expressed strong disapprobation of prayer healing, but agreed that Herr von Windheim, the Police President, must make no martyrs.

Smallpox Threatens Coronation.—With the increase in the number of cases of smallpox, London's population is flocking to insurance offices in order to get insured against the epidemic. All classes are taking advantage of the underwriters' charge for vaccinated and unvaccinated risks, though for the East End districts the premium is as high as 21 shillings. Some financial men have been insured for as much as 7,000 pounds against the risk of catching smallpox, but the average policy is about 500 pounds. It is feared that May or June will be the worst month of the epidemic. If this is true, it is a serious menace to the success of the coronation festivities.

An Antivaccinationist Convinced.—The Boston Board of Health last Saturday announced that Dr. Immanuel Pfeiffer was ill with smallpox in its worst form at his home in Bedford, and probably could not live. Dr. Pfeiffer was one of the strongest opponents of vaccination in Massachusetts, and recently appeared before the Legislative Committee to urge repeal of the compulsory vaccination law. Having the courage of his convictions, he went to Galloupes Island and completely exposed himself to smallpox with the above results.

Victims of Russian Railroads.—A recent report of the Russian Minister of Ways of Communication shows that in 1899 there were 4,447 accidents, or an average of a little more than 12 per diem. In all, 1,226 persons were killed and 6,933 injured.

British War Scandals.—It is understood that a contract for meat was first resold at £10,000 premium, and then at £40,000, while Cecil Rhodes and the De Beers group handed over £200,000, and thus finally secured the privilege of supplying the troops in South Africa with fresh meat. These figures are likely to add

fuel to the fire of public indignation which threatens to center around the British Secretary for War. Truly blood is thicker than water. It now appears that the embalmed-beef episode of our Spanish-American war need not be regarded as the result of unbridled avarice running riot in a young nation that lacked the moral restrains of long established civilization. It may have been only the outcroping of a family trait.

Banquet in Honor of Dr. Gregory.—The medical profession of St. Louis, under the auspices of the St. Louis Medical Society, will give a testimonial banquet to Dr. E. H. Gregory, who for fifty years has been an active teacher of medicine. The banquet will be held at the Planters House the early part of April. A large number of guests will be invited, including all the ex-presidents of the American Medical Association out of compliment to Dr. Gregory who was president of the Association in 1887. A Committee composed of Drs. F. J. Lutz, N. B. Carson, J. P. Bryson, C. H. Hughes, W. B. Outten and H. W. Loeb has the matter in charge.

American Hospital in Paris.—There is to be built in Paris an American hospital, where all citizens of the United States will find in case of illness careful medical and surgical attention free of any charge. Funds for the purchase of land, for the erection of buildings, for the complete fitting up of a model modern hospital and for the endowment of the same are available. In fact, the land has already been bought, and for several months American architects have been working on the plans.

Severed Twins.—On Monday last Professor Doyen of Paris did an operation upon the Hindoo twins who were united after the manner of the famous Siamese twins. The little patients were under chloroform for about twenty minutes and the operation was a success, although their condition is not promising, owing to previous tuberculous infection.

The Hugo Prize.—This prize, amounting to one thousand francs, for the best work upon a subject pertaining to the history of medicine, written in the French language within the past five years, has been awarded by the Paris Academy of Medicine to Dr. Mélanie Lipinska of Warsaw for her work entitled "History of Women Physicians from the Middle Ages to the Present Time." With the prize is conferred the title Laureate of the Academy of Medicine.

The Red Cross Society.—The Seventh International Conference of the Red Cross Society will take place at St. Petersburg in May, 1902.

Annual Meeting.—The eighth regular annual meeting of the American Laryngological, Rhinological and Otological Society will be held in Washington, D. C., June 2, 3 and 4, 1902.

Obituary.—Dr. W. Murray Weidman, one of the most eminent physicians of Reading, Penn., died suddenly of heart disease on February 8th, aged sixty-five years. He was at one time President of the Pennsylvania Medical Society, and was associated with all the leading medical fraternities in the country. He served through the Civil War.

Dr. Alonzo Boothy, a widely-known physician and gynecologist of Boston, died suddenly of heart disease on Saturday, February 8th.

Dr. James Hine, died February 11th at New Milford, Conn. Dr. Hine had been ill for a month, the result of injuries received from a fall. He was born in New Milford seventy-nine years ago and had lived there all his life. He was educated at the University of Burlington, Vt., and afterward at New York University, whence he was graduated with the degree of doctor of medicine. This profession he practised until his retirement some years ago.

OBITUARY.

PAUL F. MUNDE, M.D., LL.D.

DR. PAUL F. MUNDÉ died at his home, New York City, on the evening of February 7th, after an illness which has been serious for two months. During the last few weeks he suffered greatly, his ailment being an affection of the heart which has troubled him for ten years.

Dr. Mundé was a native of Dresden, Saxony. His father was Charles Mundé, and his mother Bertha, daughter of Baron von Hornemann, Counsellor of the King of Saxony. Implication in the Dresden uprising of 1849 forced the father to leave Saxony. The boy, Paul, began his education at the Boston Latin School, and entered Yale Medical School in 1863. He became a medical cadet in the Union Army in 1864, and after six

months of service in the field entered Harvard Medical School, from which he was graduated in 1866. The same year he went to Germany and served as volunteer assistant surgeon in the Bavarian army during the war of 1866.

Once more mustered out of the active service the young surgeon, just turning his majority, found at Würzburg the influence that was to shape his life's work—Professor Scanzoni, with whom he remained until 1870, acting as assistant to that remarkable gynecologist. The outbreak of the Franco-Prussian war drew him for the second time into the Bavarian army. He was a battalion surgeon, with the rank of first lieutenant, when the Emperor William bestowed upon him the Iron Cross for heroism in rescuing patients from a burning hospital in Paris.

Receiving the degree of Master of Obstetrics at Vienna in 1871, Dr. Mundé spent the next two years at various European hospitals, including those of Heidelberg, Berlin, London, Edinburgh, and Paris. In 1873 he came to New York, where he resided until his death.

From 1874 to 1892, Dr. Mundé was editor of "The American Journal of Obstetrics," raising the magazine to a position of preeminence in that specialty. He was one of the founders of the American Gynecological Society, becoming vice-president in 1884, and president in 1898. He was president of the New York Obstetrical Society from 1886 to 1888, and in 1887 was elected vice-president of the British Gynecological Society. He was a member of the German Gynecological Society, a corresponding Fellow of the Obstetrical Societies of Philadelphia, Leipsic, and Edinburgh, and honorary president of the International Congress of Obstetricians and Gynecologists. He was a member of the Medical Society of the County of New York, and a Fellow of the New York Academy of Medicine. In 1897 Dartmouth conferred on him the degree of LL.D.

At the time of his death Dr. Mundé was gynecologist to the Mt. Sinai Hospital, Consulting Gynecologist to the Skin and Cancer Hospital, and Consulting Obstetrician to the City Maternity Hospital. He was a member of the Union League, Riding, and South Side Sportsman's Club.

Dr. Mundé was the author of several authoritative works, among the best known being "Minor Surgical Gynecology" and "A Practical Treatise on the Diseases of Women," and he published more than one hundred contributions to current medical literature.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, February 1, 1902.

THE LIGHT THAT FAILS—THE "THOROUGH" SYSTEM IN CANCER—ELECTRICITY IN THE TREATMENT OF CANCER—THE ROYAL ARMY MEDICAL CORPS IN SOUTH AFRICA—THE ARMY NURSING SERVICE.

The light treatment of lupus and other skin affections which was introduced into this country from Copenhagen only two or three years ago has already *implanted* itself firmly, as far as apparatus is concerned, in many of our large hospitals. In London the real pioneer was Mr. Malcolm Morris, although the London Hospital, which numbers among its managers a man who has a highly cultivated instinct for advertisement, has contrived to get for itself whatever credit may be due to priority in this particular field. If there is any one within the limits of the three kingdoms who has not heard of the lamps presented to the London Hospital by Queen Alexandra and of the interest taken by that gracious lady in the patients for whose treatment they are intended, the fault does not lie with the authorities of the Hospital. The Queen being herself a Dane, and having also, be it whispered, experienced in her own royal person a little of the disfiguring handiwork of the tubercle bacillus, is naturally interested in the treatment, and the London Hospital people have worked that interest for all it is worth. They have publicly stated that they have patients waiting their turn who have no chance of being taken in hand for two years. As to their results with the light little has yet been heard, though the public is skilfully given to understand that they are marvelous. Dr. Sequeira, who is in charge of the department has, however, reported some promising work with the X-rays in cases of rodent ulcer. Mr. Malcolm Morris and others brought their results with light and the Roentgen rays before the last annual meeting of the British Medical Association, and on the whole as far as they went they were encouraging. But it is noteworthy that our British workers did not speak of either method with the confidence of the Copenhagen and Vienna physicians. Except in cases of very superficial disease affecting a limited area in easily accessible regions anything like a complete cure was practically unknown, though the improvement was very striking. Now the first enthusiasm always aroused by a new method of treatment is beginning to pass away, and the men who are ripest in judgment and experience show a disposition to hint a doubt if not to hesitate dislike. The cases of "cure" are relapsing and the "improvement" is disappearing. Even the X-rays, from which better things were hoped, are not fulfilling the promise of their early trials. The situation reminds one somewhat uncomfortably of the tuberculin "fizzle." It is difficult, however, to believe that therapeutic methods of such undoubted activity are incapable of producing a permanent effect. No echo of discouragement comes from Copenhagen, and there is still room for hope that the methods for some reason have not yet had fair play in this country. It should be said, however, that there appears to be no enthusiasm about the light treatment in Germany. This, of course, may be explained by the well-known unwillingness of our Teutonic friends to find good in anything that comes out of the Nazareth of a foreign nation. But on the other hand the results of the treatment have apparently not been particularly brilliant in France. Obviously the safest attitude of mind in regard to the whole question at present is one of expectancy.

The cancer question is agitating men's minds here in various directions. The money required to carry out the scheme of organized research to which reference was made in a previous letter is not yet forthcoming. The promoters thought they had caught their millionaire, but when he was thought to be ready to submit to the necessary depletion, he suddenly flung himself loose from the Sangredos who were preparing to bleed him. It is supposed that the refusal of the King to lend his ample countenance to the scheme inhibited the impulse to which the stimulus of the promoters eloquence had given rise. It is said that there are plenty of wealthy men who are ready to make up the amount needed, but there are signs of the usual jealousies arising among the promoters. Every one wants to play the part of high almoner of the philanthropists' bounty so as to show people that, if he is not the rose, he has lived near it and caught some of its fragrance.

The medical officers of our Army in South Africa are beginning to grumble, or, as the soldiers say "grouse," at their prolonged service in the field. The strain of work is beginning to tell seriously on many of them. It shows itself in nervous breakdown and cardiac disorder. But unless a man is utterly unfit for work he has to stay at his post, for there is no one to relieve him. The Service is grievously undermanned and already every available man is serving in South Africa. The War Office makes no effort to fill up the rapidly increasing vacancies and there is inexplicable delay in promulgating the Warrant making the new scheme, of which I sent you an outline in October, operative. There are said to be nearly 200 medical officers who have earned the right to retire, but who, owing to the exigencies of the service are not allowed to do so. The situation is very serious, and no way out of it is apparent unless the Government can manage to get men to enter the Service, or employs civilian surgeons. The latter have, however, proved so unsatisfactory owing to their distaste for discipline that Lord Kitchener has, it is said, protested strongly against more of them being sent out. He insists on

having officers of the Royal Army Medical Corps. But none are to be had and the War Office is finding that its system of deliberate unfairness toward the Army Medical Service is bearing bitter fruit.

In connection with the Army, it may be mentioned that the new nursing service has been accepted with very little unfavorable criticism. This may be due to the ignorance which except among a handful of experts prevails on the subject. The "experts" who drew it up came to the subject with absolutely unbiased minds, for with one exception not one of them had any ideas on the matter at all. The Queen took a great interest in the scheme and both Her Majesty and Lady Roberts showed a disposition to take an inconveniently active part in the organization of the service. Dr. Johnson asked if a patron was not one who encumbered with help a person able to look after himself. The "Committee of Experts" found that the same definition may be applied to royal patronesses. Among other things it was suggested to them that the service should be called after Queen Alexandra. It speaks well for the independent spirit in which they did their work that they successfully resisted the blandishments of their exalted helpers.

A NOBLE LIFE.

To the Editor of the Medical News:

Dear Sir: I feel that something more ought to be said of the life and character of the late Dr. J. T. Eskridge than will be said in the ordinary formal announcements of his death.

There are few American physicians who have done better clinical work than he, or who have written as much as he of what will have permanent value, or as nearly permanent as medical progress admits of. His recent contribution to the subject of pulse, temperature and respiration in brain disease was an elaborate, painstaking, highly valuable piece of work, and, so far as I know, surpassed any work of the kind that has been done anywhere. He had a rare faculty for exact and methodical observation, and as rare a faculty for clear and simple statement.

In addition to his professional attainments and intellectual qualities, which were of a high order, he was a man of the finest character, simple, unpretentious and sincere, gentle mannered, dignified and manly. For many years he had been on the borderland of invalidism, but in spite of this he worked as few do; he knew that he had two diseases either of which was necessarily fatal, and yet he went quietly on, cheerfully and without complaint, with a quiet courage that was worthy of a better fate.

The career of Eskridge is a fine example to others, for lives like his are the best sources of character. Such a man, though he may be only a humble doctor, is no less than a missionary and philanthropist, relieving the world's suffering, moralizing and elevating men, making them better and happier, and thereby hastening the day of universal good. J. H. McBride.

DISSEMINATED SCLEROSIS—HEMICHOREA AND PAROTITIS IN DIABETES—HEMOPERICARDIUM AS A CAUSE OF SUDDEN DEATH—INFLUENCE OF SOIL UPON COMMUNITY HEALTH—HEMIPLEGIA AND THROMBOSIS—EPIDEMIC DIARRHEA IN INFANTS—THE BOILING OF MILK—MICROORGANISMS AND RHEUMATISM.

Various matters of high scientific importance were presented before the British societies during December. Among these the following are the most worthy of note:

J. M. Finny, at the Royal Academy of Medicine in Ireland, December 13, 1901, exhibited a twenty-two-year-old girl with the typical symptoms of disseminated sclerosis. At the age of eighteen years she became completely paralyzed in the arms, legs, bladder and rectum, and suffered from large bed sores over the sacrum and buttocks. No cause for her illness could be found. For fifteen months she was a patient in County Roscommon Infirmary under the care of E. T. Blakeney. She left the institution so far recovered as to be in much the same state as that in which she was presented. The author called attention to the rarity and peculiarity of the disease and commented on the variability of its course and the difficulties produced in diagnosis owing to this variability in its early stage. He then pointed out that the signs were typically apparent in this patient, taking them in order of their prominence. These signs were complacency as to her sad lot and cheerfulness and contentment as to her surroundings. Gowers lays stress on this feature as characteristic of disseminated sclerosis, more commonly met with in females. A differential diagnosis must be made between this disease and others which in some particular feature resemble it. Such diseases are paralysis agitans, general paralysis, mercurial tremors, ataxic paraplegia, intracranial tumors, especially of the cerebellum, transverse myelitis, and, although the subject of diagnosis was not entered on or discussed, a warning was uttered as to the risk of confounding it with hysteria. This risk is present not when all the typical symptoms occur, as in Dr. Finny's case, but when they are ill-defined and varied in extent and gravity under the influence of time.

G. J. Peacocke read a paper on hemichorea and parotitis complicating diabetes. The patient was a sixty-four-year-old man admitted to the Adelaide Hospital April 29, 1901, suffering from diabetes with the usual symptoms, emaciation, thirst, and polyuria. The quantity of urine passed in twenty-four hours varied from three to five pints and quantitive analyses gave 2.7 ounces of sugar on May 7th, with some smaller quantities on subsequent occasions. Somnolence, which at times approached coma, continued throughout illness. He died May 28th, four weeks after admission. On May 4th he developed left-sided hemichorea, which resisted hyoscine, bromides and chloral. Arsenic in 10-minim and trional in 20-grain doses were given. These caused rapid improvement and disappearance of the chorea on May 13th. The second complication, parotitis, appeared May 11th, at first with little trouble, but on May 16th there were elevation of temperature and enlargement and tenderness of the parotid gland. The fever then continued until the patient's death, but never was higher than 101.6 Fahr. The cause of the parotitis was obscure. Similar conditions have been described in a variety of diseases and injuries of the abdominal organs, but thus far never in connection with diabetes.

J. Burgess gave a few notes on an uncommon case of sudden death in which the cause seemed to be acute capillary hemorrhage into the pericardium. The patient was a poorly-nourished laborer, thirty-five years old, out of employment. He did not complain of being unwell until the fatal seizure came on. Presumably while seeking employment he was noticed to fall suddenly with his shoulder against a wall and then to drop to the ground. All efforts to revive him failed and when the ambulance arrived he was dead and was taken in it to the morgue instead of to the hospital. While poorly-nourished he was not emaciated. Both

lungs were emphysematous with a large amount of muco-pus in the bronchi, but without signs of consolidation or cicatrices. The pericardium was distended with over a pint of fluid blood containing clots. Both ventricles of the heart, especially on the right side, were covered with recent lymph, which at the time could be easily detected and presented a fluffy appearance. Before removing the heart search was diligently but unsuccessfully made for the source of the bleeding. On opening the heart the valves were found normal. The entire front wall of the right ventricle was affected with almost total absence of muscle fiber. The left ventricle was nearly normal, both coronary arteries were permeable. In the right ventricle was a clot formed at the time of death. Both auricles presented nothing abnormal. Although no source of hemorrhage was discovered the blood itself no doubt paralyzed the heart and caused instant death. Evidently during an attack of acute pericarditis, associated with a previously diseased heart, a bleeding occurred sufficient, although small in amount, to cause the paralysis. The usual causes set down for hemopericardium are most commonly rupture of the left ventricle, of an aneurism or of some blood-vessel into its sac, and uncommonly the accumulation of serum or blood during the course of a cancerous or tuberculous pericarditis, or of scurvy and purpura. In this case none of these causes was present except the acute pericarditis. The hemorrhage appeared to have come from the small capillaries involved in the inflammation.

S. D. Clippingdale, at the British Balneological and Climatological Society, December 18th, read a paper on the clay and gravel soils of London and the relative advantages of dwelling upon them. He gave illustrations of his paper by a geological map of London, and by diagrams of sections of the Thames basin, showing that the soil nearest the river bed was invariably gravel, while that of the districts farther away was clay. Tables were presented giving height, elevation, character of soil, density of population and death-rate of every sanitary area of London. These statistics, Dr. Clippingdale contended, proved that living on clay was not so injurious to health as was commonly supposed, and that, as all the hills around London were of clay, they resemble a clay double basin which, if turned upset down, would become immediately drained of water. The high mortality was clearly shown by the tables to be connected with the low-lying and level districts, where the soil was generally gravel. Density, class and occupation of the population were acknowledged to be important features in determining the death-rate, but did not fully account for the great difference between the mortality upon the clay hills and that upon the gravel levels. The omission from the returns of statistics of the Registrar-General with regard to rheumatism was regretted, as this disease was well known to be influenced by the soil. In conclusion Dr. Clippingdale pointed out that the important thing was to live upon a hill; if a hill of gravel could be found all the better. There are none such in or near London, but he felt that his statistics showed that the clay hills were more healthful than the gravel levels nearer the river.

H. Handford, at the Nottingham Medico-Chirurgical Society, December 18, 1901, narrated the history of a case of right hemiplegia due to thrombosis of the cerebral veins. It occurred in a woman, twenty-five years old, three weeks after the removal of a double pyosalpinx. Death occurred three days after the beginning of the symptoms of thrombosis. At the autopsy a formed, old, gray adherent clot was found in the superior longitudinal sinus and hard, new, black clots were found in the left cerebral veins. There were no clots in the arteries, no hemorrhage into the substance of the brain, and no excess of fluid in the subarachnoid space. The fact that the walls of the superior longitudinal sinus are so fixed that alterations of its caliber did not occur as in other veins, that the veins took an ascending course and that the blood-current in them was exceedingly slow, all favored the formation of a clot in that position, and when in addition the cerebral veins were involved the condition was usually fatal.

A. Fulton read a short paper on the treatment of epidemic diarrhea in infants, advocating the clearing out of the intestinal canal, the withholding of all food for a short time, and then the giving of small quantities of the white of egg beaten up with an equal quantity of water until convalescence set in. Very small doses of tincture of opium and of acetate of lead are useful in certain cases. The preventative treatment is the sterilization of milk during an epidemic.

W. B. Ramson read a communication on the question, Should milk be boiled? His points were the ease with which milk becomes a vehicle of disease, although it may come from a healthy cow. It is frequently poisoned by dirt from the milker's hands, by manure from the stable in which the cows are milked, and by dust of all kinds which, floating in the air, settles on the exposed surface. The last accident must occur during its transportation and while standing for hours awaiting sale and consumption. It has been shown repeatedly that many zymotic diseases are traceable to the use of unboiled milk, that ten minutes' boiling will destroy hurtful bacilli, and that the value of the boiled milk as a food is equal to the value of raw milk. The author further advocated the distribution of sterilized milk by the city authorities during an epidemic of diarrhea.

F. J. Poynten and A. Payne presented a paper on the results of an experimental inoculation with a diplococcus isolated after death from the knee-joint of a man, sixty-seven years old, who had suffered from chronic arthritis. Carbolic acid had been the accidental cause of death. Several joints were found to be much damaged by the arthritis with the changes of the nature usually found associated with rheumatoid arthritis in later life. Thus, the fluid in the joint was clear and scanty and contained a small foreign body, probably consisting of organized inflammatory exudate. The cartilages were eroded and the bones eburnated. The synovial membrane was much thickened. A diplococcus was demonstrated in the unincubated and incubated synovial membrane, was isolated and grown on blood, injected intravenously into two rabbits, developing in both arthritis without valvulitis or suppuration in the viscera. One rabbit was killed on the fifteenth day. No erosion of the cartilage or alteration in the bones forming the joints was found. The other animal developed an arthritis of the right knee alone, with a wasting of the muscles of the thigh and of the leg. The animal was killed in the tenth week. The exudation into the joint was scanty, clear and sterile. The cartilages were ulcerated in some places and in others had lost their gloss. The articular surfaces of the bones were slightly flattened in places, ulcerated and their edges thickened and lipped. The muscular atrophy was quite definite. The joint capsule and the tissues about the joint were only a little thickened, but the crucial ligaments were opaque and swollen. A condition of osteo-arthritis had resulted from the intravenous inoculation of a diplococcus isolated from a case of rheumatoid arthritis. The authors pointed out that other investigators have succeeded in much the same way and emphasized the fact that the monarticular inflammation in their experiment was the result of an inoculation into the veins and not of a direct injec-

tion into the joint. They summarized their conclusions as follows: (1) A diplococcus was present in the synovial membrane of the knee-joint of a sixty-seven-year-old man. Several of his other joints showed the chronic destructive changes of one type of rheumatoid arthritis. (2) This diplococcus had been isolated and cultivated. (3) Intravenous inoculation into rabbits had upon two occasions produced arthritis without cardiac lesions. (4) The organism had been isolated from the joint exudations. (5) In one instance an osteo-arthritis, which was non-suppurative, had resulted. This special form of arthritis the authors have not previously observed in animals inoculated with the diplococcus of rheumatic fever. (6) They consider this diplococcus to be the cause of the arthritis both in the man, from which it was isolated, and in the rabbit. Cultures of this diplococcus and sections showing it *in situ* in uninoculated and inoculated fragments of the synovial membrane were shown. The diplococcus rheumaticus was also demonstrated in the synovial membrane from a case of early rheumatic arthritis. Specimens, changes within joints, and tubes containing fluid from such joints were also shown.

SOCIETY PROCEEDINGS.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Stated Meeting, Held November 6, 1901.

The President, Alexander Lambert, M.D., in the Chair.

Case of Phlegmonous Gastritis.—Dr. Alexander Lambert said that last summer a case of phlegmonous gastritis occurred in Bellevue Hospital. The patient was a longshoreman who had developed an acute mania and had gone into a stranger's room and made a scene. He had been roughly handled for his intrusion, and had then been brought to Bellevue Hospital. He was a marked alcoholic. On the fourth day he had refused his food in the evening and had been more or less nauseated. The next day he had insisted upon getting out of bed, although much weaker. On going to bed subsequently he had complained of pain around his abdomen. According to the records there had been no rise of temperature above 99° F., and the pulse had not been specially accelerated. Thirty-six hours after his first vomiting there had occurred frequent attacks of vomiting and his pulse had become suddenly very rapid. He died a few hours later at 5 a.m. At the autopsy no peritonitis could be found anywhere. The stomach weighed half a pound and the wall of this organ was half an inch in thickness, and felt boggy. Microscopic sections showed the case to be one of phlegmonous gastritis. The mucous membrane of the stomach was intact, as was also the peritoneal coat, but the submucosa between the mucous membrane and the muscularis showed an enormous number of small round cells pushing the mucous membrane and the muscularis apart. By differential staining the picture presented resembled one of erysipelas of the submucosa. The speaker said that 85 cases of phlegmonous gastritis had been reported in literature, and in half of them there had been peritonitis. As a rule, the temperature had been irregular and the pulse had not borne any close relation to the temperature. Chevosteck in Vienna and Janeway of New York had made a provisional diagnosis during life, and this diagnosis had been confirmed at autopsy, but no one had ever positively diagnosticated phlegmonous gastritis during life. These cases were interesting because of the utter lack of clinical data by which a positive diagnosis could be made. Microscopical specimens were presented.

Malignant Endocarditis with Interesting Features.—Dr. Lambert also reported this case. Clinically it had been a case of acute articular rheumatism complicated with endocarditis, which, so far as the clinical symptoms were concerned, had been of the malignant type. So far as the bacteriological examination, blood-count and the postmortem findings were concerned, it was not a malignant endocarditis, but simple, acute rheumatic endocarditis. The patient was a laborer, twenty-six years of age, with a family history practically negative. Twelve days previous to admission he had suffered from pain in the wrists and forearm and on admission there were headache, fever and swollen wrists and ankles. He was very apathetic and intensely anemic. The physical examination had shown a bronchitis, a heart of normal size and position with a forcible apex beat. There were no murmurs. The second pulmonic sound was, however, distinctly accentuated. Twenty-four hours after admission a faint blowing murmur had been audible at the apex and by the next day this murmur had been louder and transmitted to the axilla. During the next two weeks the bronchitis had cleared up although the anemia had increased and the patient had become more apathetic. At this time, on January 21st, a macular eruption had developed on the arms, neck, trunk and penis—apparently a rheumatic purpura. This eruption had disappeared in five days. A week after this the cardiac murmur had become very harsh and blowing and was transmitted to the axilla and to the back with a marked accentuation of the pulmonic sound. A few days later his mind had cleared up and a presystolic murmur had also developed. One afternoon, six weeks after admission, while sitting up in bed, he had suddenly been seized with intense dyspnea and had died in a few minutes. The variability of the quality and intensity of the murmur from day to day and the septic rise and fall of temperature had led him to the diagnosis of malignant endocarditis. Dr. R. J. Wilson had made three or four blood-cultures from this case. Every one of them had remained absolutely negative. The blood-count twenty-four hours after admission had been 8,600, four days later 16,600, one month later 7,600, and the day before death 6,200. The autopsy showed small hemorrhages beneath the pericardium and there were large clots adherent to the borders of the mitral segment and extending up into the auricles. Granulations on the valves were extensively blended with the clots. The spleen weighed 23 ounces and showed infarcts varying in age from a few hours to six weeks. Microscopical sections and cultures after death from the valves of the heart were absolutely negative. It was usually stated that malignant endocarditis is associated with a marked leucocytosis, and that this served to distinguish it from ordinary rheumatic endocarditis, but in this case, with one exception, the number of leucocytes was about normal. This patient had been seen during life by Dr. Janeway and he had made a diagnosis of malignant endocarditis.

Dr. S. Alexander asked for an explanation of the mode of introduction of the micro-organisms into the system in the first case.

Dr. Lambert said that this was a hard question to answer. It was known that leucocytes engulf bacteria and are subsequently set free by the death of the leucocytes. It was possible that in some such way micro-organisms may be introduced, but, of course, this was a mere supposition.

Dr. Alexander said that he had been making some investigations on phlegmonous cystitis and had found the mucous membrane intact on gross appearance.

Dr. R. J. Wilson said regarding the second case that he had made blood-cultures on four different occasions

and had used two ounces of blood. Each blood-culture had represented 15 minims. He would advise that there be no less than fifteen minims for each blood-culture and that several cultures be made simultaneously.

Tumor of the Prostate.—Dr. Charles Phelps presented a tumor of the prostate that had been removed three days ago by the perineal route alone. The patient was a man who had been suffering from vesical trouble for ten years. His trouble had begun with an attack of retention of urine, which had yielded without the use of instruments. Four years ago a physician in endeavoring to draw the urine had made a false passage and since that time the catheter had been used frequently—during the last six months every hour or two. Dr. Harlow Brooks had reported that sections had been taken from various portions of the mass, but that they had failed to show any malignant growth. It was a cystic adenoma of the prostate. There was a fair amount of increase in the interstitial tissue. The muscle tissue was relatively decreased, apparently from the overgrowth of the connective tissue. Some areas showed actual tissue necrosis. Evidences of inflammation were abundant in every portion of the specimen. Dr. Brooks had recently examined 34 prostates, and had come to the conclusion that these enlarged prostates are not new growths but the result of inflammatory processes. Dr. Phelps said that there had been a good deal of hemorrhage during the early part of the operation, but practically none after the prostate had been removed. He had made use of the transverse incision into the perineum and had not experienced special difficulty in removing this large tumor. About six weeks ago the man had had quite severe hemorrhages for a period of a week or ten days, but this had been the only time that there had been hemorrhages. The growth had obstructed the rectum, making defecation quite difficult.

Dr. Parker Syms asked if during the operation the prostatic urethra or any portion of the bladder had been torn.

Dr. Phelps replied that there had been no tear except in the prostatic urethra, and there was no injury of the bladder behind the prostate, and the opening, considering the size of the tumor, was remarkably small.

Dr. S. Alexander said that he had no doubt that prostatectomy would become the operation of choice in the near future for the relief of prostatic enlargement. The operative technic could certainly be improved. No one of the methods at present in vogue was perfect. The improvement would be coincident with a better knowledge by the operating surgeon of the anatomy of the prostate in health and in disease. He deprecated the making of dogmatic statements at the present time as to the merits of any operation. He said that, on account of the great variations in the shape of the enlarged prostate, whatever method was employed there would always be a necessity for the surgeon to exercise his judgment. He said that the specimen presented by Dr. Phelps was of great interest. It seemed to him, after a very brief examination of it, that the entire prostatic urethra had been removed up to the internal urethral orifice. He pointed out that the floor of the urethra along the veru-montanum was intact and he called attention to other anatomical landmarks and in this connection he requested Dr. Phelps to have the specimen examined very carefully, bearing these points in mind. Continuing, he said that some years ago he had claimed that by his method of performing prostatectomy he had preserved the entire prostatic urethra from the neck of the bladder down to the apex. He had subsequently found and called attention to the fact that he had been mistaken in this. He believed that the prostatic urethra from the neck of the bladder to the anterior margin of the veru-montanum could be preserved, but that the prostatic urethra in front of the veru-montanum was always torn in his operation. He said in order to avoid incontinence of urine it was of the utmost importance to preserve the roof of the prostatic urethra near its apex on account of the anatomical situation of the external prostatic sphincter. Dr. Alexander, speaking in regard to the pathological report on Dr. Phelps' specimen, said that it had been his experience that nearly every one could find evidence of the results of inflammation in the enlarged prostate of long-standing. He thought, however, that inflammation could not be regarded as the causative factor of enlargement. It seemed to him that it was much more likely that the evidences of inflammation were secondary. The theory that gonorrhea was the causative factor in most cases of prostatic enlargement seemed to him untenable.

Dr. R. Morris thought that perhaps surgeons had been too much afraid of removing a certain part of the prostatic urethra. Sometimes he had removed considerable sections of it in particular cases. It seemed to him not at all likely that dangerous stricture would occur at this point. If the floor would cover nicely with epithelium there would probably not be so much to be feared from the removal of a considerable portion of the prostatic urethra. He would like to know if troublesome constriction had been observed in such cases, for, certainly he had not seen it.

Dr. Alexander replied that there was no danger of stricture following prostatectomy. The danger was that incontinence might be caused.

Dr. Parker Syms said that in some of his prostatectomies he had torn through the entire prostatic urethra, though at the moment he had not known of the accident. All of the specimens, with one exception, had been examined microscopically to determine the amount of damage to the mucous membrane, and the result had been negative in those examinations. He had, however, torn through the urethra in the membranous portion and up to the neck of the bladder. His experience had been limited to thirteen cases, but in three there had been a more or less persistent incontinence of urine, though eventually all of these patients had regained control of the bladder.

Dr. G. D. Stewart said that in Dr. Phelps' case the urethra had been entered just at the membranous part. The larger part of the prostate had been enucleated from the right side, and he had taken away all of the floor of the prostatic urethra, but had left all of the roof. The opening into the bladder would barely admit the finger. He had had but little experience with prostatectomy—only six or seven cases, and several of these recent ones. Of three cases operated upon over six months ago he could recall two in which good recoveries were made with excellent control of the bladder; in another the patient was gaining, but had not thoroughly regained sphincteric control. It seemed to him that there was never any danger of stricture in prostatectomy, but chiefly of incontinence.

Dr. Phelps, in closing, said that his patient had not had gonorrhea until he had become infected from a septic catheter. As a consequence of this the man had lost one testicle.

The Roentgen Method in the Diagnosis of Renal and Ureteral Calculi.—Dr. C. L. Leonard, of Philadelphia, read this paper. [See page 305.]

Dr. Alexander said that he was glad to speak on this subject from the clinical standpoint as to the value of the work being done by those making a special study in this department. The longer he did special work himself in urinary disease the less he felt he knew

about certain methods. He was very glad indeed to avail himself of the knowledge of others, and he thought it would be well if physicians generally felt that way. As to the diagnosis of stone in the kidney, the speaker said that ureteral catheterism was talked about by so-called genito-urinary surgeons. It should be a routine in the surgical diagnosis of diseases of the kidney. In some cases catheterism of the kidney had proved very difficult in his hands, though others had succeeded readily in the same cases. He knew nothing about the complicated questions of photography and electricity involved in the use of the Roentgen rays, hence, he availed himself of the services of those who were familiar with this work. His chief difficulty had been in interpreting the Roentgen-ray pictures, and hence he relied very much upon the interpretations given by his friend, Dr. A. B. Johnson. He would not accept absolutely the findings of the X-ray, though believing it a valuable aid in diagnosis. In this respect he took the position that he did in regard to the diagnosis made by a person who examines urine and yet knows nothing about the clinical side of a given case. Dr. Alexander urged that cases demanding the use of the Roentgen rays should not be sent to an ordinary photographer, but to one who is a clinician as well as proficient in the use of the Roentgen rays. Taken in connection with other methods of examination, the Roentgen rays were exceedingly valuable. He recalled a case in which the X-ray picture gave a very strong shadow, yet there was some doubt as to its being a stone. The plate had been submitted to an anatomist of high standing, and he had decided that the position was such that it was probable that the stone was in the kidney. An operation had then been undertaken and the stone found. In two recent cases he had been certain from his clinical observations that there was a stone in the kidney, but the Roentgen rays had failed to find it. He had then treated these cases for a chronic follicular prostatitis, although the symptoms had pointed strongly to stone. He was glad to say that both cases had done well under this treatment, though without the aid of the Roentgen rays he would have felt called upon to operate for supposed stone. Mention was made of another case in which the kidney was undoubtedly enlarged and was well below the free border of the ribs. It was exceedingly tender. The ureter had been catheterized and a diagnosis made by one person of stone in the kidney, and by another of stricture. Dr. Johnson had assured him that there was no stone in this patient's kidney. The examination of the urine was negative. Since the woman had been assured that there was no danger of stone or of cancer the pain of which she had complained had disappeared.

Dr. Parker Syms said that his own experience had not been favorable as to the finality of the negative diagnosis of stone in the kidney by means of the X-ray, but he had been convinced that this was because of the difficulty of securing the services of one skilled, not only in taking the pictures, but in interpreting them. Many conditions present the symptoms of stone in the bladder or in the ureters, and it was important that the surgeon should be able to determine whether or not a stone is present. In one case in which the Roentgen rays had been resorted to by him no stone could be detected, yet almost immediately after the last exposure had been made the patient had passed a renal calculus, thus proving that the method of examination had been faulty. He hoped something more would be said by Dr. Leonard as to the details of the technic employed by him.

Dr. A. B. Johnson said there could be no question that the surgical world owed to Dr. Leonard the placing of the negative diagnosis of renal stones upon an absolutely solid foundation by means of the Roentgen ray; certainly more credit was due to him for the development of the method than to any one else. His own experience had extended over a comparatively short period, *i.e.*, eighteen months. Short as it was he would second an assertion, repeatedly made by Dr. Leonard, to the effect that, given a proper apparatus and the requisite knowledge and skill, enabling the operator not only to make the pictures but to interpret them rightly, a negative diagnosis can be made with absolute certainty. The reason the plates fail to show a stone in a case in which the stone is subsequently found, especially if the patient is of medium size and the stone of fair size, is that the plate taken by the operator is of such a quality as not to bring out the necessary details. Dr. Leonard had long ago pointed out that, unless the X-ray pictures did show a certain amount of tissue differentiation the extent of which could only be determined by experience, the plate was of no use for the purpose under discussion, although it might be able to show a large stone. The muscles on either side of the spine should show with great distinctness; the transverse processes of the last two ribs should show plainly; there should be considerable shadow of the soft parts, and usually some shadow of the kidney itself. These were the requisite qualities, and if present the stone would show. To obtain such ngeatives in a large, stout individual was not always easy. With a thick body it was necessary to increase the distance of the tube from the plate, or else run the risk of causing burns. This increased distance made the exposure longer. The picture must be exceptionally good to show a small stone in a stout person, and, as the exposure must be longer, one hesitated to take many pictures. Dr. Leonard insisted that the quality of the light given by a tube should be such as to show upon a photographic plate the greatest possible amount of tissue differentiation. This could only be done by the use of a "soft" or low-vacuum tube. A tube of high resistance and great penetration does not give as good results in this class of work. Dr. Leonard had placed an absolute limit on this resistance, using ordinarily a tube having a resistance of 1½ to 2 inches. With the particular apparatus used by him this might be all right, but with other apparatus and with other tubes precisely the same rays might be given off even though the resistance employed represented three or four inches. He understood that Dr. Leonard used almost exclusively Queen's self-adjusting tube. He had used this also, but preferred other tubes. With a larger tube, having considerably greater resistance, a much greater resistance in air could be used and yet the necessary detail be obtained in the picture. A number of cases had been cited in the paper in proof of the feasibility of detecting very minute stones in the ureter. Dr. Johnson said he would also cite a case in point. In his case there had been a shadow of a very small stone in the left ureter. A month or two later a second picture had shown that the stone had moved down. At the end of another month the stone was within an inch or two of the bladder, and about ten days later it had been passed spontaneously and was found to weigh only two grains. The value of the Roentgen-ray method was well exemplified by this case. Dr. Johnson then exhibited two typical lantern slides, one showing a very large stone in one kidney and one minute calculus in the ureter on the same side, and the other showing a stone in the ureter.

Dr. Alexander Lambert said that he had been struck with the statement made by the reader of the paper that in nine cases he had been able to assure the patient that the stone would pass and that an operation was unnecessary. This was a most gratifying advance in

surgery, both to the patient and to the physician, for, often it was a question whether the patient's condition was such as to justify a serious operation unless the latter were absolutely necessary.

Dr. Leonard, in closing the discussion, said that he had described in his paper the resistance of the tube he uses because with his apparatus this gave the best results. He had seen in Liverpool this summer a beautiful negative made with a tube representing a resistance of five inches. He agreed with Dr. Johnson that varying conditions would give different results, and that the resistance he had laid down would not hold for all operators. It was not possible to absolutely protect patients from X-ray burns because the nature of the agent used is not yet fully understood. A law had been recently passed in Austria requiring persons making X-ray examinations to be licensed for that purpose, and that most of the licences are granted to graduates in medicine. Dr. Leonard said that at the present time he places the patient on a table on the back, and places the tube above the third lumbar vertebra for the renal examination. He then uses the quality of light varying in resistance from 1½ to 2 inches in parallel spark, the resistance varying with the density of the individual and to be determined by experience. In making the pelvic picture he places the tube over the sacrum on a line joining the anterior superior spines, the tube being placed in such a way that the whole shadow of the pelvic outlet is cast upon the plate. The length of exposure and the distance of the tube from the plate vary with the thickness of the subject and the varying conditions found in individual cases. The exposure had varied in his cases from five to twenty minutes. He was now doing all his work with a four-inch spark coil, and getting more energy than formerly with a ten-inch coil. These coils had been built at his suggestion, to run from a motor generator or converter giving 20 volts and 10 to 15 amperes, and he had seen them give more energy than could be used. There were improvements constantly being made on the electrical side and in the technic and development of the Roentgen method of diagnosis.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held January 7, 1902.

The President, Joseph Collins, M.D., in the Chair.

Myasthenia Gravis Pseudoparalytica.—Dr. Frederick Peterson presented a woman, thirty-eight years of age, the mother of two children, who had been first seen by him in October, 1900. She had been sent to him by Dr. Knapp of Mount Vernon. For several weeks a difficulty in speech had been noted and also some dysphagia, the condition resembling, to a certain degree, bulbar paralysis. There was no history of specific disease or of intemperance. She had no pain, not even headache. Examination showed some weakening of one side of the mouth, slight deviation of the tongue to the right and a very peculiar manner of speech, a dysarthria that had no real resemblance to that of bulbar palsy, general paresis, multiple sclerosis or any of the common types of difficulty in speaking. It seemed almost as if it were assumed, or as of hysterical simulation. There was no atrophy of the lips or tongue, and no actual paralysis of any of the muscles or of the muscles of the throat. The gait was an imitation of a spastic gait, but without spasticity. She was anemic, very weak and with a weak pulse and heart. The pupils reacted normally. The knee-jerks were rather subtypical. There was no weakness of the eyelids, such as the ptosis described in many cases. She was pregnant and in March, 1901, gave birth to a normal child. She was seen again in May and in November, 1901. The condition of pseudospastic gait and pseudobulbar dysarthria remained unchanged at both of these examinations. There was quick exhaustion in mastication, speech, swallowing, walking, etc. This disease, the speaker said, was sometimes known as asthenic bulbar paralysis, asthenic paralysis, bulbar paralysis without anatomical lesion, or myasthenia gravis pseudoparalytica, and had been described by Erb, Oppenheim, Hoppe and many others. The symptom-complex in typical cases consisted of dysarthria, dysphagia and masticatory weakness, with corresponding paresis of the labial, glossal, palatal and masticatory muscles. The paresis might affect the upper facial muscles and those of the extremities. There was no atrophy and no signs of degenerative reaction. The sensorium remained free. The disease fluctuated from time to time as regards the severity of the symptoms. The sphincters and reflexes were not appreciably affected. The course might be periodic, acute, subacute or chronic. The prognosis was unfavorable, though patients had recovered. Several autopsies had been made with negative findings.

Dr. B. Sachs said that he had seen only one other case. In the one just presented, the clinical picture was so distinct that there could hardly be any doubt about the dagnosis. Evidently the cases were very rare, for they were not of a nature to be readily overlooked.

Dr. Joseph Collins said that he was under the impression that the case under discussion would eventually become an atypical one of glossolabial pharyngeal palsy. There was nothing in the case which reminded him of the cases of asthenic bulbar paralysis that he had seen. He would not include under asthenic bulbar paralysis any patient who presented the symptom-complex of a spastic paretic condition. It was entirely opposed to present knowledge of the disease to find exaggerated knee-jerks and tendon-jerks, and for this reason he would rule out the present case from the category of true asthenic bulbar paralysis. Moreover, the woman seemed to be beginning to develop atrophy of the lips. The first case of asthenic bulbar paralysis to be described in this country was one that he had long had under observation. That woman found that while she could chew one or two mouthfuls, she could not continue to do this. The same was true of muscular acts in general; there would be sudden evidence of exhaustion. Having gone through two or three critical periods characterized principally by the phenomena of surgical shock, she had practically recovered completely, inasmuch as there were no active symptoms of exhaustion present. Her facial muscles, though presenting no evidence of atrophy, still did not respond energetically to conscious stimuli and the gait was a somewhat shuffling one.

Dr. Peterson said that his first impression was that this was a case of true bulbar palsy, but in the year and a half which had elapsed since then there had been no true atrophy of the face, and no true spastic condition. The knee-jerks were active, but not exaggerated, and there was certainly no ankle clonus. It was very easy to demonstrate the presence of muscle exhaustion. It was, of course, possible that later the case might present the evdence of true bulbar palsy, but certainly it did not do so at present.

A Case of Morphea.—Dr. J. Fraenkel presented a young woman, thirty years of age, an artist by occupation. The family history was negative, and she had been well with the exception of a severe attack of malaria eight years ago. About five years ago blotches began to form along the course of the sciatic nerve, and were at first tender, but subsequently underwent

atrophy. When first seen by the speaker the examination of the nervous system was practically negative, but there were areas of atrophy of the skin. She had improved considerably since first coming under observation on January 29, 1901. His diagnosis was morphea or disseminated scleroderma.

Report of a Case of Spinal Cord Tumor Successfully Operated Upon.—Dr. Robert Abbe made this report. The patient was an athletic man, thirty-two years of age, who had been first seen in April, 1900. He had been well up to three years before, when after a fatiguing game of golf he was seized with pain between the shoulders. This disappeared within a few days. Subsequently he noticed that the fingers began to be numb and became flexed. Then the legs and arms became similarly affected. Dr. Dana prescribed large doses of iodide of potassium, thinking the case one of spinal cord tumor. Various consultants saw the case, but he became suddenly worse. When seen by Dr. Abbe, the fingers were tightly flexed into the palm. On April 30, 1900, he operated upon the spine, removing the laminæ of the fifth, sixth and seventh cervical, and the first, second and third dorsal vertebræ. A thin layer of a whitish substance was found bulging backward, and on cutting into it a dark tumor was revealed, which measured two inches in length and was attached to the anterior wall of the canal. On removing the tumor, the hemorrhage was not severe. Convalescence was uneventful. Some of the muscular and sensory conditions were improved. Dr. F. C. Wood, the pathologist of the hospital, reported that the tumor was a sarcoma of the spinal cord.

Dr. C. L. Dana's report of this case was also read. The symptoms began, this report stated, in 1896. They did not progress much until March, 1898. He had been first seen by Dr. Dana in October, 1898. There was exaggeration of the deep reflexes, ankle clonus and wrist clonus; there were occasional attacks of vertigo, and he was particularly sensitive to cold. There was no distinct differentiation of cutaneous sensations, though the temperature sense was rather more disturbed than the other senses. Just prior to the operation by Dr. Abbe the following condition was noted: There was total paraplegia with the legs greatly contractured; the hand was in the position of ulnar paralysis; the reflexes were all exaggerated. The right arm showed anesthesia to all forms of sensation; the left arm showed no anesthesia. Apparently the disease began in the eighth cervical and first dorsal segments of the cord. While spinal tumor had been suspected from the first, Dr. Dana said that he had been inclined to believe that there was some meningeal complication. On the whole, the picture at this time was very much like that of hypertrophic pachymeningitis. The operation revealed no meningeal complication; only tumor of the cord and the consequences of pressure.

Dr. V. P. Gibney said that he had seen this patient on June 6, 1900, and had found complete paralysis of the lower extremities associated with a high degree of spasm. The thighs were strongly flexed and the legs upon the thighs, so that the heels were pressed against the buttocks. On October 30, 1900, under gas and ether anesthesia, he had divided fascia and muscles about the hips, dividing the hamstrings and the Achilles tendon, and getting the limb into much better position. Plaster-of-Paris bandages were applied from the toes to the free ribs. A second operation was done on November 15, 1900, and by this still further correction was obtained. On January 3, 1901, all plaster dressings were removed, and posterior splints were employed in connection with traction. The spasm of the limbs grew less. On February 5th, Dr. M. Allen Starr saw the case and made a diagnosis of complete degeneration of the cord. When examined last fall it was found that the spasm was fast disappearing, and that there were little or no contractures about the joints. There was no evidence of recurrence of the tumor, and the result under the circumstances seemed to be all that could be expected.

Dr. B. Sachs said that he had reported about two years ago a case of sarcoma pressing upon the cauda equina which had been successfully operated upon. The diagnosis had been made from the area of pain and from the fact that pressure upon a definite region just to the right of the spinous process of the second lumbar vertebra caused exactly the same pain as that of which the patient complained. The diagnosis was confirmed at the operation, the tumor presenting in the incision. It was extradural and was completely enucleated. The spinal cord had not yet been invaded. If there were any reason to suspect spinal tumor the operation should be done early. In the case just referred to, if the operation had been postponed even for a short time the cord would have been invaded and paraplegia would have been the result. The inclination of the neurologists to make a diagnosis of pachymeningitis did not seem surprising, and was to be explained by the length of the tumor. Even if the case were one of pachymeningitis he did not think any harm could be done by an exploratory laminectomy.

Dr. Abbe, in answer to questions, said that the tumor was intradural, that it started in the medullary tissue and extended into the spinal canal, not into the vertebral canal, and distended the spinal cord.

Dr. Joseph Collins said that the neurologists had heretofore relied too largely upon pain in making a diagnosis of spinal cord tumor, although probably the majority of such tumors were associated with pain. He now had under observation a patient in whom the symptom-complex was an ataxic paraplegia, and he was beginning to think that the case was really one of sarcoma. Seven or eight years ago he had seen in the Hospital for Nervous Diseases a case that had been diagnosed as pachymeningitis, but some months later he had made the autopsy, and had found a tumor which could have been very easily removed by operation.

Scleroderma and Sclerodactylitis, with Some Remarks on Its Therapeutics.—Dr. B. Sachs read a paper with this title. He said that most neurologists seemed disposed to accept the theory that this disease was an angiotrophoneurosis, though many were inclined to look upon it as originally a nervous disorder. It was certainly not a purely spinal affection. There was a typical fascies of scleroderma, enabling one to make the diagnosis at first glance; he referred to the peculiarly thin nose, the hollow cheeks and the retracted lip. All sorts of therapeutic measures had been adopted without much benefit. Among the remedies which had proved of decided benefit in certain cases was thyroid extract. The first case reported by Dr. Sachs was that of a woman, fifty-four years of age, who had been first seen in November, 1891. The symptoms of scleroderma had developed four years previously. Many dermatologists had seen her and prescribed for her without the slightest benefit to the scleroderma. Thyroid extract was prescribed, and it benefited her so greatly that she continued its use without permission. When seen again some time afterward she was greatly emaciated, but all of the symptoms of scleroderma had disappeared. She was directed to stop the thyroid extract at once, and after a time to resume it, taking two grains three times a day. The speaker said that he had seen her only recently and had found her perfectly well, though it was necessary to keep up small doses of the extract or the symptoms

of scleroderma would return. The second case was that of a young woman of twenty-four, who had also been benefited by this treatment. A radiograph of this patient's hands was exhibited to show the attenuation of the bones. Another case was interesting in that the scleroderma followed an injury, the piercing of the hand by falling upon a letter file. Eight months after this injury the skin of the hands became hard, discolored and tense, and the condition was aggravated by cold weather. An X-ray picture showed no changes in the bony structures. There was such slight benefit from the thyroid extract that it was discontinued, and the man's condition remains at present unchanged.

Dr. E. B. Bronson said that a distinction should be made between simple idiopathic atrophy of the skin and scleroderma. Circumscribed atrophies of the skin occurred in various places, and although they might present a hardness it was very different from the hardness of scleroderma because there was a thinning and an atrophy which was not present in scleroderma. Scleroderma was very frequently followed by atrophy, but atrophy was not an essential part of the disease. In the so-called diffuse form there was no change in the appearance of the skin in a typical case, and the change was noted only by the sense of touch. The cases reported in the paper were of the diffuse variety, but this class of cases could be conveniently divided into a limited and a universal form. The more or less limited diffuse form came on rather suddenly after an exposure to cold or after an injury, and at first the functions of the part and the appearance were not changed, but the sense of touch would enable the physician to at once recognize the existence of scleroderma. The generalized diffuse form sometimes followed exposure, but it was more commonly due to some central trouble. It was only after some atrophic changes had taken place that there was visible loss of substance. At the stage of maturity the face of such a person was not shrunken, according to his experience—in other words, the contour was not altered, but expression was entirely wanting. The circumscribed form of scleroderma was totally different, and was called by the English by the rather absurd name of morphea. Instead of being ill-defined at the margin it was sharply limited, and was usually associated with a change of color, as a rule being darker than the surrounding skin. It often presented a lilac border. In this form there was simply a scleroderma without atrophy. In most of these cases recovery was spontaneous. Some years ago he had observed a peculiar case in which the diffuse form had been converted into the circumscribed variety or morphea.

Dr. Joseph Fraenkel said that he had seen altogether nine cases of scleroderma, and had become impressed with the idea that this term included several different conditions. There were three types, the circumscribed, the generalized and the secondary forms resulting from arteriosclerosis, chronic rheumatism and very many other causes. An example of the secondary form was a case in which the patient suffered from myocarditis and angina pectoris. There finally developed along the inner aspect of the left arm a line of induration of the skin, which ultimately became atrophied. The only variety which seemed to yield readily to the thyroid extract was the circumscribed form.

Dr. B. Sachs said that the name scleroderma was rather unfortunate, because it was evident from the radiographs presented that other tissues besides the skin were affected, only the muscular tissue seeming to be exempt. The cases described by Dr. Bronson had probably been observed in the early or middle stages of the disease. A point of value in the diagnosis was the absolute immobility of the skin, the latter appearing to be glued to the part underneath. In his cases he had used only the powdered thyroid gland, given in capsules, for, in previous years he had found the extract entirely unreliable.

BOOK REVIEWS.

Photographic Atlas of the Diseases of the Skin. By George Henry Fox, A.M., M.D., Parts VI., VII., J. B. Lippincott Company, Philadelphia and London.

In these two latest fascicles of this very desirable work the following diseases are described and illustrated: Impetigo contagiosa, lupus serpiginosus, syphiloderma pustulosum, purpura, eczema cruris, pityriasis seborrhœica, chromophytosis guttata, psoriasis gyrata, pityriasis diffusa and fibroma.

We can but reiterate our pleasure in being able to endorse this work most heartily. It is the best for its purposes with which we are acquainted.

Regional Anatomy of the Head and Neck. For Students and Practitioners of Dentistry. By William T. Eckley, M.D., and Corinne Buford Eckley. Lea Brothers & Co., Philadelphia and New York.

This book might be regarded as distinctly an application of anatomy to the science of dentistry. There are in it, however, a large number of facts which one does not often see so well tabulated in books on medical anatomy, although such facts are of importance to the surgeon and physician. An example of this is found in the discussion of trifacial neuralgia. Here the author enumerates all the possible sources of its intrinsic reflex pain and specifies a system of examination for the source of such pain which involves a perfect knowledge of the distribution of that nerve. One feature of the book is the collection of a series of valuable questions at the end of each chapter. While few of the more minute points of anatomy are touched upon by the book, it will be valuable to anyone as a means of reference or for diagnostic purposes.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

The Pocket Gray. Fifth Edition, Edited by Dr. C. H. Fagge. 12mo, 269 pages. William Wood & Co., New York.

A Manual of Clinical Diagnosis. By Dr. Charles E. Simon. Fourth Edition. 8vo, 600 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Mosquito Brigades and How to Organize Them. By Dr. Ronald Ross. 8vo, 100 pages. Illustrated. Longmans, Green & Co., New York.

A Brief Manual of Prescription Writing. By Dr. M. L. Neff. Demi 8vo, 72 pages. F. A. Davis Company, Philadelphia.

A Guide to the Microscopic Examination of the Eye. By Dr. R. Greeff. Translated by Dr. H. Walker. Demi 8vo, 171 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

The Medical News Pocket Formulary. Lea Brothers & Co., New York and Philadelphia.

A Manual of Bacteriology. By Dr. H. V. Williams. 8vo, 200 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

ORIGINAL ARTICLES.

SOME NOTES ON THE BRITISH CONGRESS ON TUBERCULOSIS.

BY E. G. JANEWAY, M.D.,
OF NEW YORK.

By request of your President, Dr. Hermann Knapp, a request at first declined, I have consented to give a brief relation about the British Congress on Tuberculosis which I attended by invitation as one of the honorary vice-presidents. I fear it may be like a twice-told tale. At the same time a symposium has been arranged on certain matters relating to tuberculosis considered at that meeting.

The Congress, which convened in London during the last week of July (22 to 26, 1901) was a marked success. The arrangements were such as not only provided for but produced an orderly meeting. Anyone who subscribed the regular fee became a member. In addition, delegates were sent to represent medical, municipal, or other corporations, as boards of health, the state government and other governments or departments. Moreover, a certain number of physicians from other countries were invited as honorary vice-presidents. Amongst these—to name only a few—were Profs. Koch, Leyden, Gerhardt, Flugge from Germany; Profs. Bouchard, Brouardel, Lendouzy, Nocard from France; and from America, Drs. Dennison, Dock, Knopf, Musser, Osler, and Adami of Montreal. This gave to the meeting an international character, instead of restricting it, as the name might seem to imply, to the consideration of tuberculosis as it affected the British nation. Too great credit cannot be given to those more particularly responsible, as it implied a great deal of very hard work on their part, not alone to arrange for the scientific and practical side of these meetings which lasted for four days, but also to fill in the gaps with social amenities for the members, delegates, and those accompanying them.

In this way there was a reception on the evening preceding the opening of the Congress, a reception at the Mansion House by the Lord Mayor and the Lady Mayoress; a reception at the Victoria and Albert Museum, South Kensington, by the Earl of Derby and the Countess of Derby; a river party at Richmond by Sir J. Whitaker and Lady Ellis, and a garden-party at Syon by the Duke and Duchess of Northumberland.

The King, who was much interested in the Congress and who as Prince of Wales had intended to preside at the opening meeting, received a certain number of the delegates from other countries. The Duke of Cambridge opened the Congress on behalf and by the request of the King at the first general meeting and received addresses from chosen representatives of foreign countries. Dr. Osler spoke for America. On the last evening the British members gave a dinner to the foreign delegates and vice-presidents at the Hotel Cecil. Throughout you will see that the foreign representative was cared for, and that not alone his knowledge of tuberculosis, but also his acquaintance with those working in the field was broadened.

The control of tuberculosis is a matter which outweighs in importance any medical question before us. All those circumstances which may hasten the time when the amount of the disease shall be lessened should be welcomed and such as may retard the event should be deplored. What we wish to know, however, is the truth regarding the conditions against which we must use the greatest effort.

At three of the general meetings of the Congress addresses were delivered as regards the means or measures which should be adopted. The first was by Robert Koch, to whom the medical world is so much indebted for his brilliant discoveries and painstaking investigations. He approached the subject from the side of its method of development and considered that all the facts pointed to the sputum of tuberculous individuals being the main source of infection. He advocated in consequence devotion of energy toward the prevention of this infecting sputum becoming a source of danger. Whatever aided this was to be encouraged—prevention of expectoration, notification of those affected with tuberculosis to public officials, and, in particular, measures such as those adopted in New York City for the disinfection, etc., of rooms. He praised Dr. Biggs for his share in this work. The lessened death-rate in England, he believed, was to be ascribed in a large measure to the hospitals for consumptives existing there, and hence he advocated the erection of special hospitals for consumptives, endowed by wealthy individuals, by municipalities and by the State. He then drew attention to the benefit of instruction of all classes of people as regards the dangers of intercourse with individuals affected with tuberculosis, and of the consumptive as to what he was to do when he coughed and how he should treat his sputum. He also spoke on sanatoria as a means of lessening the dangers from the disease, by curing properly selected cases before they reached the infectious stage. He did not believe that the statistics, particularly those in Germany, proved that we could rely on these as greatly aiding in prevention. The figures which he gave were that in Germany there were 226,000 people over fifteen years of age in such advanced stages of consumption that hospital treatment is necessary for them. The sanatoria at present existing could only accommodate 20,000 in a year, of which

judging by the past 4,000 would be freed of the bacilli in their sputum. He said that the sanatoria would never render the other measures superfluous, but, if the number become great and if they perform their functions properly, they may aid the strictly sanitary measures in their conflict with tuberculosis.

Prior to these declarations he had created much surprise to such of those who had not foreknowledge by declaring emphatically his disbelief in the identity of human and bovine tuberculosis for the following reasons: Experiments on properly selected animals (cattle) showed that the bacilli originating from human tuberculosis when inoculated or injected in cattle or when fed to them would not induce tuberculosis. Moreover, he believed that, while it was not proper to make a contrary experiment by using bovine tubercle bacilli in human beings, we had a practical experiment in the fact that milk and butter contained to a considerable degree bovine tubercle bacilli. Now, if the danger existed, as had been supposed, we should have a much greater amount of primary intestinal tuberculosis, which was found to be a very rare condition in Berlin. He said that he had conducted his experiments on animals during the past two years in order to produce this proof. His conclusion was that we could neglect the care of meat and milk as the cause of tuberculosis, using these words: "I should estimate the extent of infection by the milk and flesh of tuberculous cattle and the butter made of their milk as hardly greater than that of hereditary transmission, and I do not deem it advisable to take any measures against it." This certainly is a very important statement, so much so that Koch himself suggested that it should be confirmed by the experiment of others.

We have with us to-night the pioneer in the work of the study of the difference between human and bovine bacilli, obtained by observing the effect of injections of cultures from each source in cattle, Dr. Theobald Smith, who reported his work in this direction to the Association of Physicians in Washington, May, 1896, and who again made a second communication in 1898 to the same Association. I have asked him to be present in order that he may give you the benefit of his five years' study, experience and conclusions. In his published statement he was more cautious as regards the possibility of the infection of human beings by bovine bacilli from the udder of affected cows in the milk supplied to children. I am sure that the Academy will appreciate the presence of a quiet worker for years in this particular field and pay attention to the views which he will give us.

You may ask me what are the views which I entertain upon so important a matter? I said at London that friction will produce light and light illumination and that in the end the truth will prevail. I have had one experience within recent years which has made me cautious. This related to a group of three children in one family living in a near-by New Jersey town, affected with tuberculous glands in the neck, which were later removed by Dr. McBurney at the Roosevelt Hospital. When these children were brought to my office, I cross-examined the mother as to the origin of the trouble, and at first she thought that the milk supply was all right, but on her return home she was informed by her cook that some time before blood had been present in the milk. I immediately had word sent to the State Board of Health of New Jersey, asking for an examination which was made a week later, but in the meantime the cow which had been ill disappeared. Not alone these children, but the children of two neighbors had the neck glands affected; they all took the same milk supply. I had a careful inquiry made as to other possible sources of infection in the house, but with a negative result. It has always been a matter of regret that a more prompt investigation was not possible, for I feel reasonably sure that the source of infection may have been a contaminated milk supply. *Per contra*, a few years ago a mother brought to me her child who had drunk largely for some years of the milk of one cow which had been found to be tuberculous, and, on being killed, was found to be affected throughout by tuberculosis. Over a year had elapsed since the destruction of the cow, the child showed no evidence of tuberculosis, and there was greater danger of the mother than of the boy, owing to her extreme anxiety.

It is apt to be assumed that if a child has primary intestinal tuberculosis, this would necessarily be ascribed to the milk. Koch has stated that he has made some experiments with such tuberculosis by injecting, etc., into cattle without much proof so far, *i. e.*, if of human it ought not, if of bovine origin it ought to prove infective.

In children creeping on the floor, putting fingers and other objects in the mouth, the possibility of infection should not be lost sight of. In the case of bone, joint, glandular tuberculosis, we may not have proof of primary site of entry. My attention was particularly drawn to the possibility of infection of children in this way when, at Quarantine Hospital on one occasion, I noticed the children from a cholera ship playing on the ground and putting their hands in little pools of water and then in the mouth; cholera had been marked in the emigrant children on the steamship. Hence this exists as a possible source, providing a case of tuberculosis is present in the particular place examined or can have had access to it. I feel, moreover, that till it has been shown that milk from tuberculous cows, and especially from cows with tuberculous udders, is harmless, we must continue our efforts to obtain a pure milk supply. I cannot believe that milk from diseased cattle will furnish the food that is best for infants and children, in whom the results, even if not tuberculous, might be such impairment of health as to constitute one of the causes predisposing to a habit of body rendering it liable to an inroad of tuberculosis from some other source. In view, moreover, of the greater effect of bovine tuberculosis upon animals

other than the human, it does seem as if men might react to bovine tuberculosis when cattle would not react to human. One swallow does not make a summer, nor one case prove anything except that no harm happened to that subject.

At a subsequent meeting when tuberculin was discussed Prof. Koch was asked whether the tuberculin in use was all human or partly bovine in origin, and the inquiry was also made why should cattle react to tuberculin from human tuberculosis if insusceptible to it. The reply to the first was that it was all from human type; to the second, according to my understanding, relationship of bacilli was the explanation.

On the day but one following, Prof. McFadyean made a reply at the general meeting in a paper upon tubercle bacilli in cow's milk as a possible source of tuberculous disease in man. In this paper the main contention was, first, that the greater virulence of the bovine bacilli for other species of animals argued that it might very probably be pathogenic for man also; second, that the statistics of the hospital in Great Ormond Street, London, examined by Dr. George Still, and those of the Royal Hospital for sick children in Edinburgh, by Sheenan, seemed to point toward a greater frequency of primary infection through the intestine. The first gave 29.1 and the second 28.1 as the percentage of tuberculous infection by the alimentary tract. I have asked certain of the Fellows of the Academy to consider this question, and to state so far as they are able their experience and views on the liability of cow's milk to be a source of tuberculous infection.

Prof. McFadyean recommended: (1) Compulsory notification of udder disease, and of any symptoms of tuberculosis in milch cows, with of course the power to inflict a fine for not reporting; and (2) the interdiction of the sale of milk from any cow suffering from tuberculous disease of the udder or exhibiting clinical signs of tuberculosis. He was not inclined to believe that it was practicable in Great Britain to use the tuberculin test in all infected herds, or to compel the isolation or slaughter of all cows reacting to this test. The obstacle was that one-third of all the cows in Great Britain giving milk were tuberculous.

I trust that this short abstract will induce the members to read the entire paper, if they have not already done so. As regards Prof. Koch's paper, I presume all the members have already perused it; if not, I would urge their doing so, as I have omitted mention of some factors, such as cases which ought to be segregated and the earlier comparative allusions.

In order, however, to illustrate the difference of views which obtained, Prof. Brouardel in his address at the second special meeting laid great stress on the laws in England which were enacted for the building of better houses and for the improvement of the sanitary condition of old houses as one great cause of the improvement in the death-rate from pulmonary tuberculosis in Great Britain, which in fifty years has amounted to fifty per cent. He also laid great stress upon alcoholism as an adjuvant in the weakening of the system and rendering it liable to tuberculosis. He spoke also in favor of dispensaries for tuberculosis and of seeking out the tuberculous invalid instead of waiting until he should apply. He would have workmen as agents who would notify when a fellow coughed. He spoke also in favor of sanatoria. His paper was a review of what was being done in different countries against tuberculosis.

The Congress was subdivided into four sections, viz., (1) municipal, (2) medical, including climatology and sanatoria, (3) bacteriological and pathological, and (4) veterinary. In each of these work was carried on in the mornings, many interesting papers being read and discussions conducted. At the municipal section a paper by Dr. Biggs on "Notification" was read. It contained reasons for making this compulsory, defining what was to be understood by this and giving statistics of favorable results attributed to it. It led to considerable discussion.

The discussion of tuberculin as an agent for the diagnosis and cure of tuberculosis was also much debated. Dr. Koch was one of the principal speakers. Regarding it as a curative agent he took practically the same ground as Dr. E. L. Trudeau has taken, viz., that it was only to be employed in afebrile cases; as a diagnostic agent he had employed it in 3,000 cases without bad results. Having prevented one person from suing a physician who had used it for diagnosis, whereby rapid phthisis had resulted, I am not in the same position.

The discussion on mixed infection and phases of tubercle bacilli, etc., was also of much interest.

Interesting papers on sanatoria and on climate were presented, and the demonstration of radiographs of the lungs showing capability of demonstration of lesions of tuberculous nature was favorably received. The Academy will recall Dr. Williams's demonstration of this matter. At the Section of Veterinary Medicine the consideration of tuberculosis in cattle was discussed in its different phases.

I cannot dismiss this portion of the subject without speaking in terms of greatest praise of the Museum of the Congress on Tuberculosis and of its descriptive catalogue, compiled and edited by Dr. W. Jobson Horne, Honorary Secretary to the Museum Committee. The catalogue of one hundred and forty-nine pages was descriptive of preparations from different museums which had been gathered into a room convenient to the hall of meeting. Perhaps as interesting as any were the five culture-tubes of tubercle bacillus originally obtained by Prof. Koch in August, 1881, from the miliary tubercle of a man and carried through four hundred and thirty-five sub-cultures without again going through the animal body. The cultures of the tubercle bacillus and of organisms resembling it were also well developed. The part on morbid anatomy of tuberculosis was also very full and instructive. To

the lay mind it must have provoked thoughts of future possibilities.

To Malcolm Morris, the Honorary Secretary of the Congress, much praise should be given for those labors which were entailed by his position and to which he proved equal before and during the Congress.

The result of the Congress was given in a series of resolutions adopted on the afternoon of the last day. These were as follows: (1) Human expectoration is the chief source of danger, or cause of production of phthisis. (2) Measures should be adopted to secure the destruction of the sputum. (3) Notification is under certain conditions necessary. (4) The construction of sanatoria, especially for the poor, should be favored. (5) All measures hitherto in force against tuberculosis in cattle should be adhered to. (6) Koch's experiments should be repeated, and established by others—a committee. (7) An international committee should be formed. (8) Due consideration should be given to the contributing causes, such as alcoholism. (9) Participation in unions or associations was favored. (10) The theme for the next Congress was the individual disposition to tuberculosis.

The proceedings have been published and each of you may read for himself if these hints make you desire. I regard early recognition of the presence of the disease in an individual as a matter of prime importance, not alone for the cure, but also for prevention. Each patient whom we rid of the bacilli and prevent from reaching the advanced stage is a great gain. It seems almost superfluous to speak on this subject here and yet, unless great care is exercised in each case coming to us with a slight cough and somewhat departing from the normal healthy condition, we are liable to overlook the incipient stage of the malady. No one should be examined unless the chest be bared of all but a thin unstarched garment. Moreover, we must be on our guard not to assume that tuberculosis cannot be present should the ear fail to detect any very striking deviation from the healthy standard. Take the cases which begin with slight hemoptysis, and I suppose that you know when it has ceased, how little of a sign may be present? This leads not a few physicians to claim that it originated from the throat. We should aim at making a diagnosis before we find dulness and marked respiratory changes. These will not come with the affection of a small bronchus, but suspicious slight evidence of an apex catarrh may be made out. My own practice is to subject every case of this kind to examination of the sputum for tubercle bacilli, to comparative weighing, to study of the thermometric record taken four times daily in the rectum for a week, and to repeated examination if not satisfied. We owe to Robert Koch a debt of great magnitude for the ability to distinguish the tubercle bacillus. What course remains under these circumstances if one should still be undecided? We may act on suspicion and send the patient to a different climate and surroundings without an absolute diagnosis, or we may employ tuberculin or the iodide of potassium to increase secretion around a disease focus or the Roentgen rays (see Dr. William's work). I feel that we do not frequently enough act on suspicion rather than on proof. This method is all right for the wealthy when frankly explained, and probably for those of moderate means; but for the poor, for those dependent upon daily labor, it is an impossibility. But, as I said years ago and as Brouardel has enunciated, of what avail will it be if we seek out those who are in the incipient stage, unless we may direct them to a place where health may be restored? Of course an altered mode of life, better nutrition, and appropriate medication may restore some, even within the confines of a large city. Some undoubtedly have sufficient vitality to overcome the disease without radical change; but for the majority there is a gradual or quicker further invasion. For these we need an increased accommodation in already existing sanatoria and new sanatoria. We may search out the tuberculous invalid in the beginning of his illness, but to his cry of "What shall I do?" shall we only educate him as regards the care of the sputum to prevent him becoming a source of infection to others? Or shall we in some near future be able to say that the municipality, the State, or some wealthy philanthropist has provided a place to which he can go with a fair chance of recovery? There are certain such sanatoria in the Adirondacks, as the one over which Dr. Trudeau presides, also the San Gabriel, and one projected at Stony Wolde. There exist also the Loomis Sanitarium at Liberty, that at Bedford, and some even within the confines of New York City, but these have not sufficient room; some are not properly placed for incipient cases and some could not take care of those unable to pay for support. Yet I am in favor of a plan by which we either seek out the tuberculous invalid or else advise him to be carefully examined by a competent physician, and, when this has been accomplished, may be able to tell him go here or there for his recovery.

Dr. E. L. Trudeau the other day told me that he had thirty-five on the waiting-list of the sanatorium at Saranac. Here I wish to digress so far as to voice a word of praise for the splendid work which Dr. Trudeau has accomplished at Saranac. I can recall the look of disappointment which came over his features when over twenty-five years ago I told him that he had incipient trouble in one lung. He had then a bright future opening before him in this city, but I do not believe that he would have accomplished more for the good of others than has been his privilege in that Adirondack wilderness to which he later went for the restoration of his own health. Through his instrumentality many have been cured and many alleviated. Moreover, through the laboratory, he has done much to protect the profession and the public from injury and deceit.

Let us then ask that provision shall be made in order that the consumptive invalid can be ac-

commodated. Fellows, you and I advise people ill with this disease to go to the country. Possibly, if of little means, they seek out a farmhouse in the mountain regions, where no one watches to see that they do not become source of infection to the proprietor, to his family or to guests. This is a matter to which either the State Board of Health or local boards should give heed, and of the necessity of action I have no doubt. But the action should be reasonable, based on those requirements as regards expectoration, disinfection, etc., which exist in the city. The provision of sanatoria sufficient to take charge of these people would obviate the danger and be of distinct educational value to the invalid. This Academy has already passed resolutions asking the city government to act in this matter. Several of the Fellows interested in this phase of to-night's topic will give you their views and also statements as regards sanatoria which they represent.

Whilst the sanatoria for incipient and curable cases should be situated in the best location, it is also desirable that hospitals should be made for those far advanced in the disease, where uniformity of action shall insure the destruction of the bacillus, give comfortable surroundings to the sufferer, and prevent him being a source of danger in the wards of a general hospital. Certain hospitals already exist, and the city, as I understand, pays for the board of such as can be received at these institutions, but I am informed that there are insufficient accommodations or improper surroundings.

Some Fellow may ask, how many incipient cases are there? I think that we may look at the number dying each year as answering that question to a certain degree, *i. e.*, the number that have hitherto begun and succumbed. It does not represent the number who recover, which should be added. So we may be sure that for the Borough of Manhattan or The Bronx there are over 5,000; and with those that recover it would not be unreasonable to suppose that between seven and eight thousand people are each year made serious victims to tuberculosis.

The diminution in number of people dying of tuberculous diseases is a matter of great interest and, as I have stated, can be and was ascribed to different causes. Certainly the statistics of Great Britain show a reduction of 50 per cent. of those dying of pulmonary consumption in the fifty years since 1851. The statistics in New York, as Dr. Biggs has pointed out, show a reduction of over 30 per cent. The same is true of other places.

The practical teaching is that we must urge that the greatest possible regard should be paid to sanitary conditions in the homes of the poor; that measures should be carried out such as are in force in New York; that hospitals should be provided which can accommodate the consumptive in his later stages, so that he may not infect others in a general hospital or in the confined walls of a small home; that sanatoria whether by increased accommodation in those existing, or by construction of new, should be provided from funds given, or taxed for; that cases should be sought out in the early and more curable stage; that means should be provided which shall insure to the invalid in the early stage good food as well as medicine, when the means are too restricted to procure this; that the public education as regards the true nature of the disease should be continually carried on; that the pocket handkerchief should not be used as a cuspidor; that all conditions which weaken the body are adjuvants to the bacillus, and hence the need of instruction as to the best means of maintaining health.

Tuberculosis in other situations without secretion is not dangerous to others, nor is tuberculosis of the lung, provided no bacilli are contained in the sputum. It is dangerous, however, to have people suppose because a single examination has shown no bacilli in the sputum that their expectoration is not a source of danger.

As regards views on the milk supply, I have already spoken, and consider it desirable to continue efforts for a pure product. The following is a communication from Dr. E. L. Trudeau, who was invited to take part in this symposium, but could not be present. He will thus give you his views and experience on the use of tuberculin and on sanatoria.

"Saranac Lake, N. Y., Dec. 10, 1901.

"My Dear Dr. Janeway:

"You ask me for a few words in regard to my experience with tuberculin and sanitarium methods.

"During the past ten years I have used tuberculin, both as an aid to diagnosis and as a specific method of treatment. As an aid to diagnosis I have applied the tuberculin test mostly in suspected cases of incipient tuberculosis of the lungs, and, with a few exceptions, the test has proved reliable and has enabled me to make a positive diagnosis before this could be done by the rational or physical signs alone. I have never seen any harm from the application of the test in the class of cases in which I have used it, or any evidence that it had had an injurious effect on the tuberculous process. But of late years I have confined its application strictly to apyretic cases, or such as were nearly so. It should not be used when there is much fever, because the results obtained in such cases are apt to be unsatisfactory and misleading, and because, too, it has seemed to me that it might be unsafe, not on account of any injurious effect on the tuberculous process itself, but principally because the hyperemia it induces may tend to aggravate and intensify the secondary infection generally present to a greater or less degree in patients with any temperature above 99.5° to 100° F. Pleuritic cases, enlarged lymph-nodes, cases of slight hemoptysis without rational or physical signs, and those patients in whom a depreciation of health exists with occasional slight disturbances of temperature and no expectoration, or expec-

toration in which the bacilli cannot be demonstrated, and slight or obscure physical signs, furnish the best field for its application.

"We know that tuberculosis may exist for months and even longer before it is possible to detect it by the usual methods, and an early diagnosis is of such vital importance to the patient and to the success of his treatment that any agent which will enable the physician to make the earliest possible diagnosis should be applied in suitable cases. The tuberculin test should not be used indiscriminately or carelessly, and it is but rarely necessary to employ it.

"I have also used tuberculin as a specific method of treatment and still consider it in the experimental stage. For this reason I have confined its application to patients at the Sanitarium only, where its effects could be carefully watched. Its application in the active types of the disease, and in sufficiently large doses to produce repeatedly marked reactions, is certainly inadvisable and often injurious. In the apyretic cases, in which there is no reason to suspect any secondary infection and when the patient's nutrition is good, if given in small and very gradually increased doses so as not to produce any marked rise of temperature, its use has been found free from danger and the proportion of recoveries in the patients treated has been encouraging.

"Susceptibility to the action of tuberculin varies to a most marked degree in different patients, according to idiosyncrasy and the extent and type of disease. In some the dose may be increased quite steadily without any constitutional disturbance, while in others the slightest attempt to increase the dose will be followed by the usual symptoms of tuberculin reaction. In these the treatment will have to be extended over many months, and will require the utmost patience and caution before any immunity to the toxin is obtained. The most painstaking care and skill are necessary in the application of this method. After the patient has been brought to tolerate fairly large doses, the treatment should be discontinued and resumed after an interval of two or three months; and, if susceptibility to a repetition of increasing doses remains, a course of treatment similar to the first should be continued until full doses are again tolerated. Cases thus treated seem to show somewhat less tendency to relapse than those which recover under climatic and hygienic methods alone, and would indicate that some degree of immunity had been induced.

"Although I have used several varieties of tuberculin in the treatment of these cases, I do not feel in a position to form any opinion as yet as to the relative merits of these preparations. The method of applying such specific treatment has thus far been purely empirical and will continue so until laboratory researches throw more light on the mechanism of artificial immunity against bacterial diseases. The recent researches on hemolysis and bacteriolysis promise to advance our knowledge on this all important subject. It is evident, however, that the production of a marked degree of toxin immunity does not necessarily mean complete bacterial immunity in the disease; this treatment is still in the experimental stage and it must be admitted that it is limited to cases which are likely to recover under the ordinary climatic and hygienic treatment for the disease.

"My experience in the application of sanitarium methods during the past eighteen years has steadily increased my faith in this mode of treatment as the best means at our command to arrest and cure tuberculosis and this is becoming now generally recognized. Eighteen years ago, when I undertook to make a practical application of Brehmer's methods by founding an institution in which these could be applied in treating persons of moderate means, the advantages which the sanitarium plan offers were not understood and I could with difficulty fill the few beds in my institution. At present the benefits of sanitarium treatment have become generally accepted and the applications for admission have increased so rapidly that, notwithstanding the growth of the institution, only a fraction of those who apply can be taken and several such sanitaria could be filled in a short time.

"The sanitarium insures to the patient the best conditions for his recovery, namely, the systematic application of the open-air and climatic method; the regulation of his daily life as to exercise, food, sleep, etc.; the proper care and treatment of his case during the exacerbations and accidents of the disease; protection from the dangers of secondary infection, and a thorough education as to the future management of his case and the care necessary to prevent his being a source of danger to others. All these advantages cannot be secured in open resorts.

"It has been urged as one objection to sanitaria that the expense attending this mode of treatment puts it beyond the reach of most patients who are dependent on their own exertion for support.

"This difficulty will have to be met soon by suitably endowed institutions and by the coöperation of the State. My own institution has met it for eighteen years, and confined its work *entirely* to patients who cannot pay more than five dollars a week, the deficiency each year being made up by subscriptions of those interested in the work. Such institutions, however, should not be left dependent on so precarious a support, but should be endowed and should offer a broad field for private philanthropy.

"Although the sanitarium is but one factor in the general struggle against tuberculosis, it is one of which we stand in great need. Sanitaria tend to limit the spread of this disease, and, if it is conceded that they offer the best chance of recovery, they should be placed within the reach of all. We need more sanitaria, not only for the working classes and for people of moderate means, but for the rich as well.

"Very truly yours,

"E. L. Trudeau."

THE RELATION BETWEEN BOVINE AND HUMAN TUBERCULOSIS.[1]

BY THEOBALD SMITH, M.D.,
OF BOSTON;
GEORGE FABYAN PROFESSOR OF COMPARATIVE PATHOLOGY IN THE MEDICAL SCHOOL OF HARVARD UNIVERSITY.

IT was with considerable hesitation that I accepted an invitation to discuss the relation between human and bovine tuberculosis at this time. The events of the past few months have shown that work, rather than opinions and words, is needed to put an important branch of our sanitary service on a firmer basis. The present occasion, I realize, needs a broad general statement of the problem and I have therefore omitted all technical details which I hope to incorporate with some new matter in a later paper. I furthermore realize that any position taken to-day may have to be somewhat modified when confronted with the results of experiments likely to be made in the immediate future on this now engrossing subject.

In general, my standpoint to-day does not differ from that of 1898, when I stated that a beginning had just been made by a recognition of the bovine bacillus as a race or variety of the mammalian stock of tubercle bacilli. With this point gained, the next step was to trace this bovine race into the human body and in this way gain an insight into its transmissibility. But it required the authority of a Koch, reversing his own long-standing conclusion, to awaken the lethargy of investigators, start new commissions, and arouse the opposition of public-health and other officials whose labors in the suppression of bovine tuberculosis seemed about to be blocked by forces always prepared to fight anything opposed to their personal and material gain. The situation is thus a very complicated one and views and opinions must somehow be accepted as working hypotheses to keep the machinery of public health in operation. With this fact as a guide I venture to review the situation and present views which have forced themselves upon me in endeavoring to get at the actual state of affairs.

That human and bovine bacilli are not necessarily identical occurred to me nearly ten years ago in watching the effects of the inoculation of bovine virus, infected milk and sputum upon guinea-pigs. The character and progress of the guinea-pig disease was highly suggestive of variations in virulence. Differences of this nature could be demonstrated only with pure cultures, because then the number of bacilli injected could be made approximately equal. When, in 1894-1895, I isolated and studied a bovine culture and one from an animal (*Nasua narica*) domiciled with a tuberculous man, the great difference in virulence as tested on cattle, as well as certain morphological differences, impressed me with the idea that distinct races of the tubercle bacillus existed. In 1896 these studies were again taken up in the then newly-established laboratory of comparative pathology of the Harvard Medical School and with the aid of the Massachusetts State Board of Health, and in 1897 a sufficient number of pure cultures had been isolated to enable me to test the bovine and the human cultures on cattle in parallel series. The coöperation of the Massachusetts Cattle Commission, through its chairman, Dr. Austin Peters, enabled me to test ten cultures on as many cattle. The outcome confirmed earlier studies and led me to state that we are justified, "if only to guide and stimulate further study, in establishing a distinctly human and a bovine variety of the tubercle bacillus."

The bacteriological method is not the only one which must be applied in putting the bovine bacillus into its proper place, but I think that it forms the key-stone of the arch without which facts and observations obtained by other means fail to hold their place. It will eventually serve to clinch arguments from all other sources.

Among these the records of clinical observation have occupied a very conspicuous place in the polemical literature of this subject. Placed by itself, the evidence which they present is, I think, inherently weak. We all know on what slippery ground we stand when we endeavor to trace the etiology of an infectious disease without recourse to the laboratory, with its more penetrating, analytical methods. The difficulties are greatly increased when we try to find with absolute certainty the source of infection in a subject as little under control in his movements as man and in a disease as insidious in its beginnings as tuberculosis. Clinical observations are, however, of very great value in forming the foundation of the bacteriological work and in guiding the bacteriologist to the most promising material for study.

The cases of direct inoculation as reported by Ravenel, Salmon and others cannot decide the question for us. An inoculation does not under all circumstances correspond to natural infection. Animals which are susceptible to certain diseases by inoculation do not necessarily contract them by cohabitation. Cowpox as a derivative of smallpox is an inoculable, but no longer a contagious disease. Again, the production of a limited amount of dead tissue in a wound may give the requisite impetus to an organism otherwise overcome or repelled at the start by the natural protective agencies. This brings before us that important, still unsolved problem, the phenomena attending the beginnings of infection, especially on the mucous membranes. It is quite possible that something interferes with the absorption of tubercle bacilli of bovine origin which lets human bacilli pass. Or, it may be that if human bacilli are absorbed only with difficulty in the intestines this difficulty is greatly increased for races of bacilli specifically modified by adaptation to other species.

One phase of the clinical problem which has created little attention is the possible infection of the human subject through the infected air of cow-stables. The great majority of cases of bovine tuberculosis are the result of infection

[1] Read at a meeting of the New York Academy of Medicine, Dec. 19, 1901.

through the air. In 1894 I carefully analyzed my autopsy notes of 88 cases of the bovine disease and found 85 with lesions of the thoracic organs. Of these 41 were evidently discharging tubercle bacilli from disintegrating foci in the lungs. Here a rich field of activity presents itself for the tubercle bacillus from cattle, but we have as yet no evidence whatever that human beings are infected in this way. Physicians favorably situated should give cases among dairymen careful attention and bring them to the notice of the bacteriologist for study.

Turning to the bacteriological aspect of the subject upon which I have already touched and taking into consideration the comparative studies of bovine and human bacilli made by the writer, Vagedes, Dinwiddie, Ravenel and Koch, we may now maintain without fear of contradiction that the bovine bacillus presents certain traits which serve to distinguish it from the great majority of bacilli isolated from the human subject. These traits or characters are not the exclusive property of the bovine bacillus as contrasted with those from human sources. I am merely emphasizing the constancy of such characters and not their peculiarity.

Morphologically the bovine bacillus multiplying on coagulated serum is uniformly short, never slender or slightly curved, as is the case with many human forms. Culturally it grows with great difficulty even on serum and I have not been able to make it grow on glycerin-agar at the start. Later these difficulties disappear under artificial cultivation. Other minor differences will, I think, be found in the near future. As to virulence this is quite uniform and very great for rabbits, whereas the majority of human cultures are not. The difference between human and bovine bacilli in their effect on cattle is now well established. Koch emphasizes the increased virulence of bovine bacilli for horses, swine and sheep.

Tuberculins made at the same time from cultures of both races have been repeatedly tested by me upon tuberculous guinea-pigs. No appreciable differences were noted in the effect produced. The tuberculins made from bovine cultures have been used by colleagues in the diagnosis and treatment of this disease in man, and, so far as I have had verbal communications, the results did not differ from those obtained from tuberculin made from human cultures. The same was found true in regard to its use on cattle. This identity of action must not surprise us. The subtle race differences could hardly be expected to survive repeated and prolonged boiling.

When we come to sum up the characters of human bacilli we find much less uniformity. The cultivation is as a rule easier, but variations occur. Some bacilli are so saprophytic in their tendencies that they grow from the start on glycerin-agar. Others refuse to do this. Some grow in moist glistening layers, others in the more common, dry, scaly or nodular masses. Bacilli from some cultures are short, resembling the bovine type, others are long and slender. The special form is as a rule preserved for years in cultures. Slight variations in the culture media, though they may have a temporary effect on the form, do not persist when we return to the original media. Only after years of cultivation changes of outline are occasionally noticed which, I think, are referable to the capsule. The virulence likewise fluctuates, but in none of my cultures was there any approach to the virulence of the bovine race. This may have been simply an accident. Vagedes, who isolated a series of twenty-eight human cultures, describes one which seems to have had the characters of the bovine race.

It was obtained from a girl, fifteen years old. She entered the hospital November 12, 1895. Both parents and a brother and a sister had succumbed to tuberculosis. The girl had both apices affected in June, 1894. In November, 1894, both lungs were extensively infiltrated. There was high hectic fever. Death ensued May 24, 1896. Both lungs and intestines were found involved.

It is somewhat remarkable that this exceptional culture of Vagedes, described in a work done under the direction of Koch himself, was wholly ignored by the latter.

Lartigau in a recent study of nineteen human cultures is inclined to regard one of them as of bovine origin.

A more thorough study of similar bovine-like bacilli to be found in the future and the inoculation of young cattle with them, in addition to rabbits, which species I regard as very valuable in making a preliminary distinction between these races, are obviously the next steps. If we should in any case of spontaneous tuberculosis isolate bacilli agreeing morphologically, in virulence, and in the character of the tissue reaction of the inoculated animals with the bovine bacillus, we must be prepared to concede the case as one of bovine origin. But, assuming this point to have been gained, there are other questions growing out of it.

1. What is the reason for so few positive infections with so much opportunity given for infection through dairy-products?

2. Is there any ground for assuming a modification of the bovine into the human type in the body of man and in this way accounting for more positive infections?

Taking up the first question I am inclined to believe that racial differences are operative in preventing the absorption of the bovine bacillus under ordinary circumstances by mucous surfaces. I say absorption, because in early life the type of disease approximates that of cattle, in that the bacilli tend to pass through the mucosa to lodge and multiply in the lymph-glands. This similarity must not be construed as pointing to an identity in the etiology. I am further inclined to believe that when infection does occur certain pathological conditions, among them traumatism, are present to favor it. Hence the belief which now seems to gain ground and which I voiced in

1898 that a few bacilli are harmless, but that the flooding of the digestive tract with bacilli from tuberculous udders is dangerous. In the latter case the bacilli are continually present and prepared to act at any time when the conditions become favorable.

The second question involves fundamental principles of etiology. To what extent is the bovine bacillus modifiable in the human body? Can it lose its identity therein? In order to state the case as fairly and judiciously as possible I presented this possibility of modification in 1898 in the following way: Can a long sojourn of the bovine bacillus in the human body lead to its gradual modification so that, entering by way of the digestive tract it may eventually appear in the sputum from the phthisical lung with only a moderate degree of virulence? The only facts we have at present to keep this hypothesis before us is the wide range of virulence of human bacilli, from saprophytized forms unable ever to infect a normal body, but only capable of acting as secondary parasites, to those forms approximating the virulence of the bovine type.

The modification of bovine bacilli in the same human body beyond recognition as such by the bacteriologist, if it ever occurs, necessarily presupposes a prolonged sojourn, probably of years, at the shortest. This again implies an initial resistance of the human system to the high degree of virulence of the bovine bacillus whereby only a mild type of tuberculosis results. While I accept the possibility that bovine bacilli may change if they multiply in the human body, I do not believe that such a change can take place excepting after a number of passages. The experiments of Vagedes and my own (unpublished) indicate that passages through rabbits do not perceptibly modify the bovine bacillus. Hence, in searching for a direct infection from cattle in infants or children for example, especially in the primary foci of the mesenteric glands, I am of the opinion that the bovine bacillus, if there, would be found with undiminished virulence. If it should become modified after a long stay in the body of resistant adults, future study may be relied on to find the successive stages of modification.

On the whole, if we accept the hypothesis of a modification in the same individual, we acknowledge thereby that the human body is capable of exerting a specific resistance over the bovine bacillus which largely neutralizes the high potency of the latter.

The modification of bacteria is not sufficiently understood at present to afford any sound basis for our attitude toward bovine tuberculosis. Used without restraint, it may be made to prove anything. Thus we may, with its aid, assume, as has been done repeatedly, that all human tuberculosis is bovine in origin. The highly potent virus entering the human body becomes attenuated and when it is discharged in the sputum it is no longer infectious, or it may lose its power to infect after several passages through human beings. Thus, the cow would be the source of all active virus. But the bovine virus is propagated from animal to animal chiefly in the same way, *i. e.*, through sputum, yet it does not appear to be losing its virulence. These hypotheses are given to illustrate the importance of steadying the flights of our imagination by chaining it to patient research within and without the laboratory and accepting only those premises which have successfully passed a severe scientific scrutiny.

Even the hypothesis that the bovine bacillus may become modified in the human body leads us to the same inference already reached—that a few tubercle bacilli are harmless, because the specific resistance which we must assume as existent would easily take care of a few bovine bacilli.

It seems to me that the only way to refrain from doing violence to the accumulated knowledge of bacteriology is to take the ground that the bovine bacillus, if it invade the human body, should appear as such in our cultures. Especially in the young should this be our guide, for tuberculous lesions of the abdominal organs, the mesenteric glands in particular, in children are not so old as to jeopardize the identity of a bacillus which maintains unimpaired for years its morphological and physiological characters in our cultures. The investigator, however, must keep before him the possibility that bacilli from one species grafted on another may become altered.

I am loth to leave this subject without calling attention to the possible aid we may derive from comparative pathology in a problem of such importance as this. Man is but one of a species of mammals, and in the search for fundamental principles we will fail if our studies are confined by the traditional boundaries of human pathology. When we come to the working-out of details we must return to the species the advancement of which we have in view.

As regards the transmissibility of bacteria, racially related among themselves, from one species of animal to another certain facts are at hand. There are several large groups or races of bacteria besides the tubercle bacillus which exercise a wide influence upon animal life. One of these comprises the races of the so-called rabbit-septicemia bacillus. Here we have bacilli indistinguishable from one another which produce epizootics among mammals and birds. But it is becoming more and more evident that these races are pathogenetically distinct. Only last year a striking illustration of this fact came to my notice. In conjunction with Dr. Cooper Curtice of the Rhode Island Experiment Station I isolated a race of this species from a highly fatal septicemia in geese which was of maximum virulence to rabbits. Although this species has been known for many years, since the earlier labors of Pasteur, to produce fowl-cholera, yet this particular race, so fatal to geese, had no effect on other fowls. Epizootics due to this bacterium among buffaloes, according to Von Ratz, did not pass to cattle, a species also subject to an infectious disease due to another variety of this bacterium.

Similarly the large group of pathogenic derivatives of bacillus coli affect many species of mammals and some birds and occasionally man in epidemics of meat-poisoning. These varieties maintain indefinitely their minor differences in cultures and in their activities they are sharply confined to a particular animal species. They are also differentiated by the agglutinins which they call forth in the immunized animal.

On the whole, the student of comparative etiology is inclined to regard the apparently identical, or, at most, but slightly divergent races of such bacteria as transmitted only sporadically and under special conditions to species other than the one in which they regularly cause disease only sporadically and under special conditions. Ordinarily the plagues or epizootics are sharply delimited in spite of the constant intermingling of different species of animals. Everything points to the theory that the particular variety produced by adaptation has gained something as well as lost something during this period of adaptation which makes it act successfully toward a certain species or a narrow group of species only.

Nor does it seem that a bacterium which has gained the power to act upon some large powerful species, like the ox, necessarily acquires thereby the power to attack smaller species. Thus, the bovine tubercle bacillus readily invades swine, but I have been unable to produce any effect on mice with it. We have within recent years had our attention forcibly called to the peculiar susceptibility of man to a disease of the rat, while spontaneous infection of species other than rats and mice by the plague bacillus is not yet confirmed.

Tuberculosis passes from man or cattle under certain conditions to dogs and cats. These animals will, I believe, furnish evidence of value in the problem before us. I have thus far had the opportunity of isolating and studying comparatively cultures from three cats and one dog. Should I draw any conclusion now I would say that they are from man. In any event we have here the important habit of flesh-eating to consider in its relation to the races of the tubercle bacillus.

The glanders bacillus furnishes still another illustration. The transmission of glanders from the horse to man is a firmly established fact. When we, however, take into consideration the large number of glandered horses found each year and the number of persons who come into close contact with such animals, the transmission from beast to man dwindles into a rare occurrence.[1]

Summing up the evidence from comparative pathology, I should say that we have no right to assume the indiscriminate transfer of bovine bacilli to man without thorough investigation. For we know that there are no *a priori* rules to guide us in predicting the susceptibility of any animal species toward any variety of micro-organism. There are no natural groups of animals which react alike toward bacteria. Each species is a physiological unit by itself, possessing certain relationships to other species which only experiment and observation may discover. The remarkable studies on hemolysis by Bordet, Ehrlich and others, pay ample tribute to this fact. It is equally obvious that we are not justified in accepting at present the sweeping, and what appear to me hasty, inferences drawn by Koch from his experiments that the bovine bacillus cannot invade the human body. As the broad student of infectious diseases Koch is correct, I think. The differences between bovine and human bacilli are too striking to lead the experimenter to any other preliminary conclusion at first. The study of details and the example before us of a great range of species occasionally invaded successfully by tubercle bacilli soon convince us that exceptions may occur and that the next step is to discover how often and under what conditions we may look for them.

The conclusions which may be drawn provisionally from the foregoing may be tersely stated under the following heads:

1. There is no evidence to show that bovine tubercle bacilli may indiscriminately infect the human subject.

2. There is some evidence that bovine bacilli have been isolated from human beings, that the successful transfer is uncommon and that it depends on certain conditions which need careful clinical and pathological study.

3. The evidence that such transmission takes place must be based on the isolation of tubercle bacilli having the characters of the bovine variety.

The attitude which these conclusions would lead us to assume toward bovine tuberculosis, at least for the present, does not differ appreciably from that now generally maintained. Periodical rigid inspection of dairy-herds, looking toward the elimination of all animals with suspicious disease of the udder or tending toward emaciation should be maintained. Beyond this sanitarians cannot well go, but every effort should be made to encourage publicly by suitable official recognition those who use the tuberculin test in purifying dairy-herds. Bovine tuberculosis is at best an agricultural calamity and its widespread diffusion and frightful ravages should arouse even the most conservative to bring about by individual effort rather than with the help of the public purse the rehabilitation of the dairy-cow.

[1] The Cattle Commissioners of Massachusetts state in their report for the year 1900 that 699 animals were killed as having glanders or farcy. There were reported to them during the same year two undoubted and one doubtful case of the same disease in man.

A PLEA FOR AN ACCEPTED NOMENCLATURE WITH REFERENCE TO THE CLASSIFICATION OF PULMONARY TUBERCULOSIS.[1]

BY J. EDWARD STUBBERT, M.D.,
OF NEW YORK;
PHYSICIAN IN CHARGE, LOOMIS SANITARIUM, LIBERTY, N. Y.; PROFESSOR OF PULMONARY DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

It is not my intention to present a long paper to explain theories or statistics; but rather

[1] Read before the American Climatological Association, 1901.

to set forth a few statements showing the inaccuracy of statistics as compiled to-day by various observers on tuberculosis, with the hope that the few ideas presented will provoke a discussion which will lead to the adoption by this Society of certain fixed definitions that shall be accepted as the basis upon which all statistics must be built in order to enjoy the confidence of the profession at large, and, especially, to merit consideration by scientific observers. No one, I believe, will doubt either the necessity for some common and positive basis upon which to build statistics and compute results, or the fact that there is no Society in this country or abroad the scope of whose work or the standing of whose members renders it as capable of deciding the question before us.

While statistics are, to some extent, unreliable, we cannot dispense with them. All conclusions must be derived therefrom, and yet great confusion exists, not only in conclusions so drawn by widely-separated observers, but among those intimately associated in work. In Massachusetts, we find Bowditch and Otis widely divergent upon the definitions "cured," "apparently cured," or "arrested cases"; while in New York we find as wide a difference of opinion between Trudeau, Baldwin and the writer in defining the difference between "apparently cured" and "arrested" cases. At the meeting of the Medical Board of the Loomis Sanitarium, held in New York about three years ago, there were present Drs. Polk, Loomis, A. A. Smith, W. Walker, Quimby, F. Miller, Chappell, Markoe, Beverley Robinson, and the writer, and yet no two men held exactly the same opinion as to where the dividing lines should be drawn between the incipient and moderately-advanced, or between the latter and the far-advanced stages of pulmonary tuberculosis.

There are, then, two conditions to be classified: (1) The condition of the patient when he comes under observation and treatment; (2) the condition that exists when he is discharged from the physician's care. Under the first heading, we have to deal with three, and, possibly, four, conditions: (*b*) Incipient; (*c*) moderately advanced; (*d*) far advanced; and, as a fourth, but naturally preceding the others, (*a*) variously designated as the "pretuberculous" or "prebacillary" stage.

By a large number of physicians, including such men as Baldwin, Trudeau, Knight, Babcock, and Bowditch, a "pretuberculous" stage is not recognized, but accepted as a general dyscrasia, such as might precede the development of any infectious disease; or, in other words, that would make infection possible. I find, however, that a few, *viz.:* Baldwin, Babcock, Bowditch, Brown, and Janeway, will allow the term "prebacillary" while objecting to the term "pretuberculous," although the majority do not think the term necessary. Another physician (Brown) considers the term "prebacillary" as synonymous with the incipient stage of tuberculosis; two others (Loomis and Ingals) see no difference in the meaning of the two terms.

The definition, gathered from the different ideas, is as follows: One in which tuberculosis is suspected, but where the symptoms are slight and bacilli can not be found in the expectoration. No one, however, has suggested what name shall be given to moderately or far-advanced cases in which tubercle bacilli are not present.

Others again, notably Ingals and Hance, affirm their belief in a so-called "pretuberculous" stage, which they define as follows: A condition in which the physical signs are indefinite, and in which there are loss of weight and strength, a rapid heart action, slight fluctuation in temperature, and sometimes a slight hacking cough.

In comparing notes on the definition of an incipient case, I find that Loomis, Trudeau, Knight, Babcock, Bowditch, Hance, and Ingals agree in all essential points, the following being the general idea gained by such comparison: Slight physical signs of limited extent in one or both lungs, with or without bacilli in the sputum, with or without slight constitutional debility or complications. Another authority (Hance) recognizes such a stage only when bacilli are present together with the usual symptoms; and another (Baldwin) claims that slight physical signs may be present or absent, provided the rational symptoms point to such a condition.

As to the definition of the term "moderately advanced," I find an agreement in the most important points in the opinions of Loomis, Baldwin, Trudeau, Hance, Knight, Babcock and Brown. The definition is as follows: More or less well-marked constitutional symptoms, with extensive signs in one or both lungs; or where there is only a slight amount of pulmonary involvement, with very severe rational symptoms. Another noted physician (Bowditch) is more reserved, and does not allow the term if there is evidence of decided consolidation or cavity formation; while still another (Ingals) relies solely on the extent of the physical signs.

There seems to be a general harmony in the definition of the term "far advanced," the composite idea being: A far-advanced case is one in which there are extensive physical signs with or without cavity formation, and in which there is severe constitutional disturbance, with or without complications.

Once we are finished with a patient, it becomes a question of even greater importance how to properly classify or index him. Shall we declare him "cured," "apparently cured," "arrested," or "improved"? Here again we find a wide divergence of opinion among competent observers. Very few are willing to declare a patient cured until a considerable length of time has elapsed without manifestation of any symptoms of the former disease. Ingals and Baldwin say that they require a patient to pass at least two years free from all signs of disease, rational or physical. Another physician (Loomis) makes the same requirement, except that no time limit is

given. Brown, Trudeau, Hance, and Knight do not use the term. Ingals and Babcock consider the term synonymous with that of "apparently cured." Bowditch classifies all such cases as "arrested." The term "cured" seems to be in disfavor with the majority of those whose opinions were received, while that of "apparently cured" appears to be the most acceptable.

Probably the greatest difference exists in the definition of the term "apparently cured." Some observers, such as Trudeau, Brown and Baldwin, place the time limit at three months, the writer at six months; while two others (Loomis and Hance) give no time limit; another one year; some others, two or three years; and one (Babcock) considers the term as synonymous with "arrested." A composite definition, leaving out the question of time, would be: Absence of all rational symptoms of disease, and disappearance of nearly all physical signs, or only those that would be indicative of scar tissue.

Apropos of this subject, I would like to submit the following statistics: Out of a number of cases at the Loomis Sanitarium, there was a reappearance of bacilli in seven cases after having been absent for three months; in three cases after having been absent four months; in three cases after an absence of five, six, and seven months, respectively, and in one case after disappearing for three and one-half years. However, in this last case it should in justice be stated that the patient has never been free from a condition of chronic bronchitis since she was seven years old.

We now come to the term "an arrested case." Again, there is great confusion as to the exact meaning of the word. As to the time limit, Knight and Trudeau agree that a quiescent condition should exist for several months, while Babcock and Bowditch say months or years. Baldwin places the time limit at two or three months, while Ingalls, Hance, and Loomis make no arbitrary rule.

As to the question of the presence of bacilli in the sputum, Brown, Babcock, Bowditch, Knight, and Ingals claim that bacilli must be absent; while Loomis, Baldwin, Hance, and Trudeau declare a case "arrested" while bacilli are still present, provided, of course, the general condition and physical signs justify such a term. A fair definition compiled from the opinions of the majority, leaving out the question of time, would be: Absence of all constitutional symptoms, including cough and expectoration and, therefore, bacilli; physical signs to show no further activity, although the limits of diseased areas may remain the same.

In regard to the last term to which I call your attention, namely, "improved," I am glad to say there is a very general agreement, a good idea being given by the following: Lessened or improved symptoms, local or general, or both. The only point of difference noted is that the majority require both local and general improvement, while a few require only an improvement in general condition.

Special work has grown so during the past few years, sanatoria and hospitals for the care of these patients are multiplying so rapidly, it would seem not only wise but imperative, from a scientific standpoint, that now, before the machine becomes too unwieldly and greater confusion has been created by lack of harmonious work, a more or less fixed definition of these various stages of pulmonary tuberculosis should be determined upon. Then statistics from all recognized sources can be worked together harmoniously and deductions of scientific value may be realized.

Supplement.

Prebacillary or Pretuberculous Stage.

"The condition of an individual whose family history, personal appearance, physique and age, experience has proven in the majority of cases, antedate the active development of tuberculosis. This stage is generally marked by persistent chloranemia, uncontrollable digestive disturbance, inexplicable rapid heart action, and progressive loss of weight."—H. P. Loomis.

"Prebacillary, meaning 'closed' or non-ulcerated tuberculosis, could include all cases described by certain writers as pretuberculous, which, according to their own description, are nearly always already infected, and the symptoms clearly secondary to such infection. Prebacillary is likely to confuse, as some very acute bad cases reveal bacilli. I should prefer to use it in a very restricted sense, or to dispense with it altogether. Definition: No symptoms and no bacilli. 'Pretuberculous' stage not necessary."—E. R. Baldwin.

"Not recognized."—E. L. Trudeau.

"Terms synonymous. Definition: Slight hacking cough, with some languor and emaciation, but no expectoration, and no distinct physical signs."—E. Fletcher Ingals.

"Pretuberculous stage designates the time antecedent to that in which physical signs and microscopical examination indicate disease; evidences of impaired health, loss of weight, strength, rapid heart action, slight fluctuation in temperature, general malaise, anemia, etc."—I. W. Hance.

"I do not think the term should be used; it is not properly applicable to any infectious disease."—F. I. Knight.

"There is no pretuberculous stage. There may be a prebacillary stage, if by this term is meant a stage in which no bacilli are contained in the sputum, but if there is tuberculosis there are certainly tubercles. Always supposing that by a pretuberculous stage was meant a latent tuberculosis."—R. H. Babcock.

"Great objection to term 'pretuberculous.' Prebacillary' stage is permissible because of cases in which tuberculosis is suspected, but no bacilli can be found, or only after a length of time. I do not like to use the term 'prebacillary.' "—V. Y. Bowditch.

"Prebacillary (excluding tuberculous pneumonia and miliary tuberculosis). Definition: In-

cipient stage before ulceration. Pretuberculous stage not necessary; often erroneously applied to the early part of incipient stage."—Laurason Brown.

"A prebacillary stage is one in which tubercle bacilli are absent, and frequently expectoration also. In a minority of cases there will be found by blood examination a certain amount of anemia, with loss of weight, possibly digestive disturbances, or physical signs may be totally, or almost totally, absent. By X-ray examination there must be shown a very slight haze, generally at one apex. Very often in these cases suspicious sounds may be elicited at the apex, which would not be detected without attention having been first called to them by the aid of the X-ray, and which would not be positive enough to base a diagnosis upon alone; and unless a shadow were discovered by the X-ray, we would not be justified in diagnosing them as cases of tuberculosis. I have never seen a case where suspicious physical signs were accompanied by a slight haze, shown by the X-ray, in which the subsequent history of the patient did not prove the correctness of the original diagnosis. I do not recognize the term 'pretuberculous.' "—J. Edward Stubbert.

Incipient.

"Slight localized lesion, with or without bacilli, and but little constitutional disturbance (fever, loss of weight, etc.)."—H. P. Loomis.

"Symptoms with or without early physical signs of limited extent in one or both lungs; with or without bacilli in the sputum; with or without slight constitutional debility or complications."—E. R. Baldwin.

"Cases in which both the physical and rational signs point to but slight local and constitutional involvement."—E. L. Trudeau.

"Involvement of apex low as the first interspace; a few râles, feeble respiratory murmur, and moderately harsh expiratory sounds."—E. Fletcher Ingals.

"Physical signs and rational symptoms are both slight; tubercle bacilli are present, and evidence of toxic infection small."—I. H. Hance.

Same as Trudeau.—F. I. Knight.

"A stage in which symptomatology and physical signs point to tuberculosis without mixed infection."—R. H. Babcock.

"Very slight signs in one or both apices; exceptionally in one spot elsewhere; little or no fever, and general symptoms are not those showing that the disease has taken any general hold upon the patient."—V. Y. Bowditch.

"Slight local, with little or no constitutional involvement."—Laurason Brown.

"Slight localized involvement of the lung, with or without constitutional disturbances."—J. Edward Stubbert.

Moderately Advanced.

"Lesion involving one lobe of one or both lungs, and in which there may be excavation; constitutional disturbances, anorexia, and loss of weight present."—H. P. Loomis.

"Symptoms are more or less marked with extensive signs in one or both lungs, beginning or actual cavitation, with or without constitutional debility or complications."—E. R. Baldwin.

"Cases in which the localized disease process is either extensive or in an advanced stage, or where, with a comparatively slight amount of pulmonary involvement, the rational signs point to grave constitutional impairment or to some complication."—E. L. Trudeau.

"Involvement as low as third rib, or a corresponding amount in another portion of the lung."—E. Fletcher Ingals.

"All rational symptoms present in severe form; evidences of a very active disease present over varying areas; may have small areas of disease with very severe rational symptoms, or the lesions and rational symptoms may both be very great."—I. H. Hance.

Same as Trudeau.—F. I. Knight.

"Stage in which there is mixed infection with signs of softening, but not any considerable destruction of lung tissue."—R. H. Babcock.

"Well-marked symptoms of a catarrhal condition of the lungs, with evidences of decided consolidation, or still less of cavity formation."—V. Y. Bowditch.

"Localized disease process extensive or in an advanced stage, or slight local pulmonic invasion, with rather marked constitutional involvement, or with complications."—Laurason Brown.

"More general consolidation of the lung with more marked constitutional disturbances and beginning of softening, or a single cavity without very marked constitutional disturbances, and with a small area of lung involvement."—J. Edward Stubbert.

Far Advanced.

"Extensive involvement of the pulmonary tissue, generally more than one lobe in each lung. Marked constitutional debility, and often complications are present."—H. P. Loomis.

"Symptoms of long standing with extensive signs with or without large cavities; marked constitutional debility and complications."—E. R. Baldwin.

"Cases in which both the rational and physical signs warrant the term."—E. L. Trudeau.

"Involvement as low as the fifth rib, or lower, with cavities."—E. Fletcher Ingals.

"All rational symptoms of severest type present; destructive process and progressively increasing areas of disease present in lung; complicating tuberculous diseases in other organs."—I. H. Hance.

Same as Trudeau.—F. I. Knight.

"Well-marked cachexia with or without extensive caseation and excavation."—R. H. Babcock.

No definition.—Laurason Brown.

"Consolidation, cavity formation, and symptoms of general infection are present."—V. Y. Bowditch.

"Extensive area of involvement with soften-

ing and excavation, and with marked constitutional disturbances."—J. Edward Stubbert.

Improved.

"Local lesion becoming quiescent, and constitutional symptoms decreasing."—H. P. Loomis.

"Lessened symptoms or signs; improvement local or general, or both."—E. R. Baldwin.

No definition.—E. L. Trudeau.

"Diminution of cough and expectoration, increased flesh, greatly diminished râles, and nearly normal temperature."—E. Fletcher Ingals.

"Some bettering of rational symptoms, with little or no progress of pulmonary lesions."—I. H. Hance.

No definition.—F. I. Knight.

"Vague and relative term. Would involve a lessening of all symptoms, and a gain in weight, without signs of extension of disease."—R. H. Babcock.

"General symptoms, cough and expectoration have diminished, with increase of strength, and possibly of weight, there being of course, different grades of improvement as slight or marked."—V. Y. Bowditch.

"Physical signs showing process less active, or general health improved, with symptoms relieved or abated."—Laurason Brown.

"An improved case is one in which the constitutional disturbances are removed, and signs of activity in the lung are reduced; the temperature is normal, or nearly so, and the patient able to return home and do a fair amount of work without exacerbation of existing symptoms."—J. Edward Stubbert.

Arrested.

"Lesion fibroid, with the physical signs of this condition; constitutional symptoms absent; bacilli present."—H. P. Loomis.

"Three months without fever or other symptoms of disease progression; partial or complete recovery of general health, without loss of expectoration or baccili."—E. R. Baldwin.

"Cough, expectoration and bacilli still present, but in which all constitutional disturbances have disappeared for several months, the physical signs being interpreted as indicative of a retrogressive or arrested process."—E. L. Trudeau.

"Absence of cough and expectoration; general good health; absence of all râles and marked diminution of dulness, with cessation of much of the bronchovesicular breathing formerly present."—E. Fletcher Ingals.

"Rational symptoms have almost wholly disappeared, and physical signs show no further activity in pulmonary lesions; bacilli still present."—I. H. Hance.

"Absence of all constitutional symptoms, pulmonary conditions being stationary, and therefore no longer active. Such an improvement must have existed for many months, or even years."—R. H. Babcock.

"All cases in which cough and expectoration have ceased, and where the general condition would indicate outwardly a return to health, regardless of the fact as to the exact condition of the chest itself, even though in many cases, so far as the physical signs themselves were concerned, the term 'cured' might possibly be justified. On account of the treacherous nature of the disease, am unwilling to use the term 'cured' until after the lapse of two or three years, possibly, when no return of the symptoms had been manifest."—V. Y. Bowditch.

"No activity in process in lungs, with absence of fever and other constitutional symptoms for at least two months."—Laurason Brown.

"Cases which have previously shown marked constitutional disturbance, but in which all constitutional disturbance has disappeared for several months. Physical signs interpreted as indicative of arrested process."—F. I. Knight.

"An arrested case is one in which all signs of activity and all constitutional disturbances have been absent for at least two months. Bacilli may or may not be present."—J. Edward Stubbert.

Apparently Cured.

"Absence of bacilli. The local changes recognized only those of complete fibrosis; no constitutional symptoms."—H. P. Loomis.

"Three months without any symptoms of disease progression; complete recovery of general health, and absence of bacilli or expectoration during whole period."—E. R. Baldwin.

"Cases in which rational signs and bacilli have been absent for at least three months, or who have no expectoration; any abnormal physical signs remaining being interpreted as indicative of a healed lesion."—E. L. Trudeau.

"Absence of all symptoms of disease, and disappearance of nearly all signs for a period of two years."—E. Fletcher Ingals.

"All rational symptoms have disappeared, and physical signs show no evidence, or but slight evidence, of scar tissue remaining. No bacilli."—I. H. Hance.

Same as Trudeau, except time limit should be one year instead of three months.—F. I. Knight.

"After lapse of two or three years, during which time no symptoms had been manifest."—V. Y. Bowditch.

"Practically synonymous with arrested. If lung were fibrous and tubercles calcareous, condition would certainly be cured. It is possible for old cheesy areas to be incapsulated and thus produce no local or general symptoms, yet the patient could not be said to be cured; it would constitute a relative cure."—R. H. Babcock.

"Abnormal physical signs absent or slight, indicative of healed lesion; absence, for at least three months, of constitutional symptoms, and of bacilli in sputum."—Laurason Brown.

"One in which the above conditions have existed for six months."—J. Edward Stubbert.

Cured.

"Absence of bacilli; no evidence of any localized pulmonary process (even fibroid) changes. Lungs normal."—H. P. Loomis.

"Two years without relapse. Not in favor of word."—E. R. Baldwin.

"Same as apparently cured."—E. F. Ingals.

No definition.—Hance, Brown, Trudeau, Knight.

"Synonymous with apparently cured."—R. H. Babcock.

"Only after a lapse of two or three years. I do not use term, but include all such cases under head of 'arrested.'"—V. Y. Bowditch.

"Those in which all constitutional signs of disease have been absent for two years and in which, for some length of time bacilli have not been found; and in which the physical signs are such as can be justly attributed to scar tissue, or are totally absent. Expectoration may or may not be present."—J. Edward Stubbert.

DISCUSSION.

Dr. Bowditch: As to the use of the term "pretuberculous stage," I must confess that I dislike it almost as much as that much-abused term "heart-failure." It seems to me that a case must either be tuberculous or it is not. I acknowledge that the gentlemen who recognize that condition are men whose opinions are entitled to great weight, but I cannot agree with them. As to the term "arrested," I think I stand alone, perhaps, in not using the terms "cured" or "apparently cured" when the patients are discharged from my care even when the general condition and physical signs would seem to warrant the latter terms. There will always be differences of opinion on this question, but I have seen so many cases discharged as "cured" or "apparently cured," and yet the day afterward, possibly, a hemorrhage or even death occurred, that I have adhered to the more conservative term thus far in my nomenclature. I was somewhat vague in my reply to Dr. Stubbert as to the length of time after which I was willing to consider the case cured. I am willing, however, to accept the time stated by Ingals and Baldwin; say, perhaps, two years.

Dr. Edson: Not being Germans we are deprived of the advantages of long words to explain our meaning. It seems to me the term pretuberculous or prebacillary stage is a good one. So much depends on the secondary infections, *et al.*, that the stage in which the tuberculous process is slight, one without any breaking-down in the covering as it were of the inflammatory area, as compared with that in which the breaking-down has occurred, and until which period we do not get the sputum, is one that may be substituted for the less wieldly one of "no bacilli in the sputum." Those cases, as a rule, have a longer and more manageable course as regards comfort and length of life than those in which general ulceration occurs.

Dr. Quimby: Ever since I began the study of physical diagnosis I have been impressed with the indefiniteness of the terms used. Some years ago, at a meeting of the Section on General Medicine of the New York Academy of Medicine, to test this question of uniformity in the use of physical diagnosis terms, I brought in several patients with well-marked signs, and, after marking a point on each chest where there was a distinctive sound, I asked the gentlemen present to listen at those points and to write down the name which they would give to each sound, folding the paper each time so that the one following could not see what had been written. Some five or six responded and when the lists were read, incredible as it may seem, no two men gave the same name to any one sound. At our meeting in Bethlehem, I read a paper on "Definite Records of Physical Signs," believing that such records can be made; but now we are discussing definitions of things which are indefinable. Our difficulty, and apparently the cause of our controversy, lies in the fact that, having applied names to confessedly mere probabilities or physical prophecies, we act as though the use of those names affirmed the probabilities to be demonstrated facts. We are attempting to affirm future conditions from present symptoms, which is, of course, impossible. Nevertheless, there is a certain something which we wish to talk about, and if we will simply agree among ourselves just what combination of symptoms and physical conditions these several apparently prophetic terms shall be accepted as indicating, we can then discuss these questions intelligently, at least among ourselves, and by sticking to them very likely bring others to accept our definition. I therefore move, Sir, that a committee be appointed to draw up a statement setting forth the combinations of signs and physical conditions which these several terms shall be understood to imply when used by members of this Association.[1]

Dr. Wilson: I want to second Dr. Quimby's motion, and my main object in doing so is that I may say a few words from the standpoint of one who is a general clinician, perhaps in contradistinction to the methods of those more interested in sanitarium work and who feel obliged, by the exigencies of their own every-day work, to use such terms, in order that a set of definitions may be brought into practice which will pass current among all interested in the subject. It seems to me that the whole set of terms we have been speaking of would indicate a want of recognition of the pathological changes which arise under different circumstances in pulmonary tuberculosis. In the first place, we do not recognize the fact that pulmonary tuberculosis is, in the beginning, a local infection, and that it often remains so, especially in cases where recovery takes place. Secondly, that there are cases that live with physical signs that are permanent, and which at no time can be shown to have had the tubercle bacilli in the expectoration. Then there are other cases of fibroid changes, starting perhaps in the pleura and extending to the lung, without giving rise to the presence of bacilli in the sputum, but

[1] The President appointed the following gentlemen as members of a Committee on Nomenclature, to report at the next meeting of the American Climatological Association: Drs. C. E. Quimby, E. R. Baldwin, F. I. Knight, V. Y. Bowditch, and J. Edward Stubbert.

leading to disturbances of the health in a lasting way. We must think, on the other hand, and I am now speaking of the difficulties we must encounter, of the recovery that often takes place which is permanent, but in which the most marked physical signs remain, such as cavities, deformities of the chest, etc. When we consider these things, the question of the presence or absence of physical signs must be considered as militating against the use of such terms as "improved," "arrested," "restoration of health," and the like. I want to say a word in this connection on a subject that has attracted my attention more and more in the last few years, and to which I have learned to attach a great deal of importance, a physical sign that is often the only one of an incipient pulmonary tuberculosis, and that is interrupted respiration. I have recognized this sign over and over again at a time when there was great question as to the patient's health, and at a time when no other sign could be elicited. I have found it in regions of the chest where other signs have appeared later. In the textbooks this sign has been given altogether too little attention. If we entertain the pathological view that pulmonary tuberculosis is an infection, then it is a mistake to make a subdivision such as "prebacillary stage" and "incipient tuberculosis," for every case that shows the physical signs or rational symptoms due to tuberculous infection is a case of tuberculosis from the beginning.

Dr. Minor: While willing to second Dr. Quimby's motion, I am rather pessimistic as to its outcome. Words, as the Frenchman said, are a means of concealing thought, and no two men will ever ascribe the same meaning to the chosen words. The reasons why these misunderstandings will always remain are that the examinations are made by different men and, while all are able, they disagree because of their different mental attitudes. As regards Dr. Stubbert's plan to classify the cases when discharged, that has been tried in Germany and failed; yet, although it seems almost hopeless, it is important to form some kind of a classification for those of us who have to report on the condition of our patients on discharge. I consider that two or three years at least ought to elapse before a case is considered cured, whatever the findings, and until then the case can only be called "arrested." I always put my patients before leaving to the test of taking violent exercise to see whether they will show any temperature. I have also laid considerable stress upon the restoration of the normal or nearly normal chest circumference, and the condition of steady weight, a weight which holds, although it is not necessarily the weight of previous good health.

Dr. Bonney: I have been for several years heartily in accord with the suggestion made by Dr. Wilson with reference to the undesirability of the terms that have been used. Four years ago I read a paper before this Association in which I made some allusion to classification. I am skeptical about the practical utility of the terms that have been suggested, and I think that each writer in reporting his cases should define his position in order that his readers can have a clear understanding of what he means. I have frequently seen cases that might be reported as incipient where the prognosis, I would think, was considerably less favorable than other cases that might be reported by the same man as advanced cases, if we depended alone upon the area or degree of pulmonary involvement.

Dr. Shurly: I am in accord with Dr. Quimby's motion and efforts. There is no use in taking trouble, and "crossing the bridge before we come to it." As long as we have to communicate with one another by language, the more nearly we can get to uniformity in every particular, the more intelligently can we discuss matters. I think this body is the one to make this effort; and though we may not succeed at first, we shall eventually if we keep at it. Some persons may not want to call a certain muscle the sartorius, while the majority of us would continue to know it by that name.

SOME NOTES ON THE PROPHYLACTIC SCREEN IN THE TREATMENT OF TUBERCULOUS CONDITIONS OF THE LARYNX AND PHARYNX.

BY STEPHEN W. WELLS, M.D.,
OF LIBERTY, N. Y.;
RESIDENT HOUSE PHYSICIAN, LOOMIS SANITARIUM, LIBERTY, N. Y.

HAVE you ever paused to consider the risk the laryngologist runs in the daily treatment of a large number of tuberculous throats? Perhaps not, so I take this opportunity to bring to your notice a screen designed to protect the face of the operator from all discharges from the throat of the patient under treatment. Many persons may have excellent control over the larynx and pharynx, but, notwithstanding this, at the most unexpected moment the patient may gag or cough and thus send out a considerable spray of the secretions from the diseased throat. Its usefulness is especially appreciated in those advanced cases of tuberculous laryngitis in which all muscular control has been lost, and the patient, in the effort to relieve himself, cares but little in which direction he coughs, and so often deposits his sputum outside the receptacle provided. The spraying of the physician by these sufferers might be considered simply disagreable were it not for the fact that we know that tubercle bacilli are present in varying numbers in the small particles of sputum thus thrown out. It was appreciation of this danger of infection to the doctor doing throat work at the Loomis Sanitarium that suggested the idea of the prophylactic screen to Dr. Stubbert, the Physician in Charge.

The screen consists of a sliding iron upright set in a weighted base; at the upper end of the upright is attached a metal frame holding a glass plate, 13" x 15", which can easily be removed and cleaned. The frame is attached to the upright so that when in use the right arm is but

one-third the length of the left arm. This arrangement permits considerable freedom in handling the instruments on the right, while the left hand is passed under the screen, thus easily controlling the laryngoscope.

I have used this screen for several years without the slighest inconvenience, treating daily an average of twenty to twenty-five tuberculous throats in all stages of the disease. I should be loth to do this class of work now without the screen, especially as I know of one case in which tuberculosis was contracted in this manner. To demonstrate further the utility of the screen, a series of experiments were made as follows:

The glass plate was rendered sterile by a thorough scrubbing with green soap and boiling water, after which it was immersed in 95-percent. alcohol, then exposed to the sunlight for a few hours. At the beginning of the throat treatment hour the screen was placed in position to receive the small particles of sputum coughed out or exhaled by the patients during the hour. These particles, some so minute as to be scarcely seen, others nearly as large as a small pea, were allowed to dry, then scraped off and collected in a test tube containing sterile water and allowed to stand until a sediment formed. The sediment was then stained in the usual manner for sputum

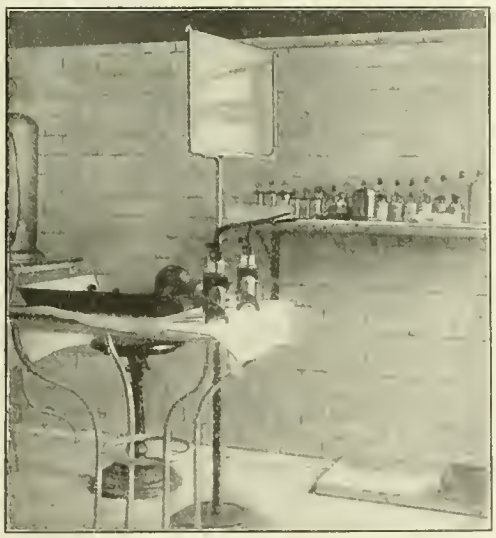

Fig. 1. The prophylactic screen.

and examined microscopically. Tubercle bacilli were found four times in a series of six experiments, varying in number from three to fourteen bacilli in each stained specimen. Several preparations were made from each of the collected scrapings.

From cultures made on glucose agar and grown in an incubator for three days, the following germs were isolated: Staphylococcus pyogenes aureus (most numerous), 1,000; streptococcus pyogenes, 1,000; micrococcus tetrogenus, 800; diplococcus pneumoniæ (A. Fraenkel), 1,000; bacterium pneumoniæ (Friedlander), 800.

It is said that a certain number of germs must find entrance into the tissues before they can overcome the natural cell-resistance of the structure and establish a colony. This number must, of necessity, vary considerably with the difference in resisting power in the individual. There-

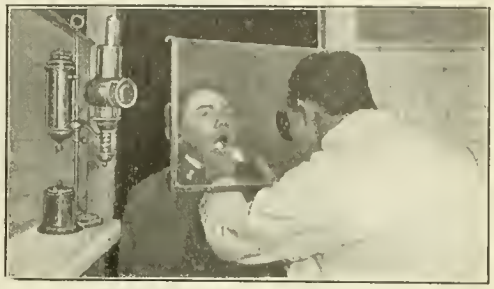

Fig. 2. The screen in use.

fore, a man, in the best physical condition, might for years treat tuberculous throats with impunity, all bacilli that he might inhale being promptly destroyed by the vigorous cell-life. But should he be unfortunate enough to contract an acute disease of the bronchi or lungs, or even a chronic condition causing congestion, the presence at such a time of tubercle bacilli might easily be a most important factor in determining the course and character of the disease. To meet this ever-present danger the prophylactic screen was brought forth without the knowledge of an earlier invention in which the screen, instead of being portable and solid, was suspended from the ceiling so as to hang between the physician and patient.

Our prophylactic screen has the advantage of being adjustable to any height; it can be easily placed in position; it does not interfere with the view of the larynx; it relieves the patient to feel that he cannot cough into the physician's face, and it thoroughly protects the physician. As to disadvantages, it has none.

THE PATHOLOGY AND THE ETIOLOGY OF PROSTATIC HYPERTROPHY: SUPRAPUBIC DRAINAGE AND MYOMECTOMY CONSIDERED AS METHODS OF TREATMENT AND CURE.

BY AUGUSTUS CHARLES BERNAYS, A.M., M.D., M.R.C.S. LOND.,

OF ST LOUIS;

PRESIDENT ST. LOUIS ACADEMY OF MEDICINE; CHIEF SURGEON TO THE LUTHERAN HOSPITAL; CONSULTING SURGEON TO THE CITY AND FEMALE HOSPITAL OF ST. LOUIS, ETC.

THE terrible sufferings which are caused by a lasting retention of the urine and the dangers to life which accompany it, as well as their relative frequency in old men, were well known to the physicians of ancient times. Hippocrates mentions this condition and adds that it is incurable. This opinion of Hippocrates was held by physicians for many centuries. Morgagni in his "Epistolæ de sedibus et causis morborum," printed in 1761, was the first to shake this pessimistic

opinion by his researches. He showed that the ischuria and concomitant difficulties of defecation were due to enlargement of the prostate. John Hunter corroborated Morgagni's assertion and devotes one chapter in his "Treatise on the Venereal," London, 1786, to prostatic hypertrophy. He mentions the difficulties of micturition in old men due to enlargement of the prostate and gives some illustrations of specimens. Everard Home in his practical observations on the treatment of the diseases of the prostate gland (London, 1811 and 1818), as well as Desault and Bonet, who were pupils and followers of John Hunter, also corroborates Morgagni's discovery of prostatic hypertrophy and its concomitant evils.

Up to the present time the etiology of prostatic hypertrophy has not been cleared up. A completely satisfactory explanation of the process has not been found. Sir Henry Thompson defined it as an "idioplastic tumor" in his lectures, which I had the great pleasure of hearing. Enlargements of organs during the early and middle life partake largely of an inflammatory nature or are found to be small-cell infiltrations. Knowing that old age somewhat inclines toward or favors the development of tumors, we are not surprised to find that a part of the sexual system may show a non-inflammatory enlargement at a time when this system, in all its other organs and in its functions, is undergoing a retrograde metamorphosis and is being more or less put to rest. However, let us remember that Sir Henry's definition is not explanatory in any sense and leaves the etiology of our subject in the dark.

Reginald Harrison seems to think that the hypertrophy is caused by overexertion or overwork of the organ the function of which he conceives to be that of aiding the bladder in the evacuation of its contents. He thinks that the main purpose of the prostate is to furnish a muscular support "primarily to the bladder and its contents and secondarily to the adjacent parts," and thus seems to regard enlarged prostate as a form of compensatory hypertrophy similar in its etiology to the well-understood hypertrophies of the muscular walls of the heart. Guyon's theory is opposed to this view, he regarding the hypertrophy as due to arteriosclerosis of the urogenital tract.

White agrees with Velpeau that in this disease we have an analogue of the fibromyomatous uterus. Sir Henry Thompson also favors this view, and I also think that the myoma of the prostate is analogous to myoma uteri and I think that it may be referred to developmental or congenital cell-nests which lie dormant in early life and are only incited to late enlargement by the incidents accompanying the functions of the genito-urinary organs in health and in disease.

Thus, we must admit that the etiology of prostatic enlargement is not understood and that the speculations which we have before mentioned are only a little more respectable than those speculations which bring diet, occupation, modes of living, abstinence and indulgence, sexual habits, gout, rheumatism or gonorrhea into direct or indirect etiological relation with the disease.

In most of the diseases in which the etiology is not cleared up the pathology is also incomplete. In the disease under discussion, however, the numerous researches by pathologists and by practical surgeons have almost cleared up the pathological anatomy of, and also added to the knowledge of, the functional disturbances which we observe as the symptoms of prostatic hypertrophy.

Cancer, sarcoma, tuberculosis, and echinococcus are rare diseases of the prostate which produce enlargement of the organ. Adenoma rarely occurs, but the hypertrophy of the prostate under discussion is of very frequent occurrence in the aged. In a study of one hundred men over sixty years of age, and taken consecutively as they came before me in my work in St. Louis, Missouri, I made a rectal examination in each with a view to determine the size and condition of the prostate. Of this number only fifteen complained of symptoms which were undoubtedly due to hypertrophy, but there was noticeable enlargement in thirty-one cases without any functional disturbance. These data, being based on a physical examination of the living patient, are probably not as reliable as the figures of Von Dittel and Sir Henry Thompson, who examined cadavers. The former found 22 per cent. and the latter 34 per cent. of enlarged prostates in cadavers of aged men, the exact ages not being known in all the cases. I have twice found enlargement of the gland, in the form of nodules, in boys; these observations were accidentally made upon two brothers, aged seven and nine years, who had died of diphtheria, and I am of the opinion that these small interstitial myomata will be quite commonly detected if looked for by those who have opportunities of frequently examining the prostate glands of young men and boys upon the dissecting-table.

Prostatic hypertrophy when microscopically examined is found to consist of an increase of the non-striated muscle cells and connective tissue which lie between the tubular glands. These latter are displaced by the hypertrophic muscle fibers, and in extreme cases are nearly absent. All of the fibrillary connective tissue found in enlarged prostate can be seen to originate from the perivascular sheaths.

We are justified in denominating the condition, which we find in most cases as myomatous hypertrophy, or, if the myoma assumes the shape of a tumor, we may speak of a myoma or fibromyoma of the prostate. In rare cases the enlargement depends upon a hyperplasia of the glandular structure, and then we may speak of diffuse or circumscribed adenoma of the prostate. The cases of acute swelling of the prostate partake of an inflammatory or infectious character and do not come under the scope of this investigation, but their existence is undeniable, although I have never witnessed an autopsy on a case of acute prostatitis.

Hypertrophy may be found in a diffuse form,

so that all parts of the organ are affected alike and there is an even enlargement of the whole gland, or tumor-like nodules, sometimes as large as a walnut, may be found in the form of hyperplastic knots of tissue which are plainly visible upon sections made through the organ. The ordinarily cylindrical urethra is changed into a vertical, narrow slit, sometimes one and a half inches long, having the enlarged lateral lobes on each side of the urethra, the sides touching each other in the median line. All parts of the organ may be hypertrophied, but there are certain parts which are favored and most frequently attacked. Mercier was the first to show that the hypertrophy usually begins at or near the isthmus of the gland and that it frequently forms what we call the middle lobe, which projects into the bladder near its neck in the form of a teat. Behind this lobe is the so-called recessus or cul-de-sac, in which the residual urine accumulates. In other cases the lateral lobes or only one of them may become hypertrophic.

The cause of the sufferings of prostatics, as well as the danger to which they are exposed, is the retention of urine which often occurs as a result of the hypertrophy. Hypertrophy of the prostate does not always lead to retention of urine, and it is often the enormously large prostate of unchanged contour which does not produce essential or severe troubles. The more localized hypertrophy affecting only one part upon one side, a symmetrical hypertrophy, as it were, or a small degree of enlargement, may cause severe troubles. This takes place when such parts of the organ are affected by the growth as are in close relation to the lumen of the urethra and project into the canal or neck of the bladder as they increase in volume.

A hypertrophy of the lateral lobes may and often does compress the urethra laterally and change it into a vertical narrow slit. When only one lateral lobe is more enlarged than the other the urethra is laterally displaced and pushed out of the median line.

Mercier proved that the hypertrophied teat-like middle lobe will obstruct the internal orifice of the urethra when the bladder is contracted for the purpose of micturition. He claims that an evacuation can only take place after a greater distention of the bladder by the accumulation of more urine is accomplished. But as soon as a part of the urine is discharged the valve will again become sufficient and prevent complete evacuation.

Thus, the residual urine is accounted for in a simple mechanical way, and we can easily understand the interruption of the stream and the tenesmus or strangury. We can understand the somewhat paradoxical phenomenon of incomplete evacuation while the patient can voluntarily pass urine. I have the conviction that this valve-like action of the middle lobe is only possible when it is very small and thin, but that it acts more like a dam when it is broad and stiff.

There are some cases in which the internal urethral orifice projects into the lumen of the bladder. It looks much like the portion of a virginal uterus when the hypertrophic growth of the prostate has grown upward and backward into the bladder. In a case of this kind the urethral opening will be closed or narrowed and will be projected into the cavity of the bladder as the muscular coats contract. The mechanics of this condition seem to be that the urine contained in the bladder will exercise an even pressure from all sides upon the cervix-like prostate, and the more pressure that is exercised by the muscular wall of the bladder upon its contents the more will the urethra be compressed and the more difficult will be the voiding of the urine. In this form of hypertrophic prostate there will be nothing to hinder the introduction of the catheter.

In old men there is always more or less of a cul-de-sac at the posterior lower part of the bladder, and we can readily see how an enlarged middle lobe must help to increase the size of this excavation. According to Dittel[1] and his assistant, Schustler, middle lobes of the prostate without enlargement of one or both of the lateral lobes is very rare. I have seen but one case of solitary enlargement of the middle lobe. According to my own observation the most usual form of prostatic hypertrophy is the bilateral enlargement of the lateral lobes in a nearly symmetrical form; when one lobe grows more than the other the one will bulge over and cause a depression in the other and the urethra will be compressed or completely closed so that the urine cannot escape. In this condition the mouth of the urethra is not the cause of the retention as much as the two opposite contiguous lateral lobes of the enlarged prostate.

The first bad effect of retention of urine, when not relieved by the catheter, is upon the walls of the bladder in a purely mechanical way by pressure of the mass of urine on the vesical wall. This, of course, causes dilatation of the bladder. The long-continued exertion of the muscular coat in trying to expel the urine will make greater demands on the muscular coat, and the constant efforts to overcome the obstacle will be responded to by a compensatory hypertrophy of the muscular layers of the bladder-wall. The result will be a peculiar netlike concentric hypertrophy of the bladder, which is known as trabecular bladder (vessie en colonne) so often seen at autopsies on patients who had narrow urethral strictures. The intravesical pressure frequently causes diverticulæ and pockets to form by the bulging out of the mucosa between the muscular trabeculæ.

A chronic and extreme retention of urine causes final dilatation of the ureters and of the pelvis of the kidney, and may cause an absorption by pressure of the secreting tissues of the kidney. When the entire urinary system or canal is thus dilated the valvular opening of the ureters which is effected by their oblique entrance into the bladder is overcome. The vesical orifices of the ureters are found widely patulous. The dammed up urine in the bladder, in the ureters and in the pelvis of the kidney form an uninterrupted column

[1] "Contributions to the Knowledge of Prostatic Hypertrophy," Medicin. Jahrbücher, Zeitschrift der K. K. Gesellschaft der Aerzte in Wien, Volume 24, 1867.

of fluid in a single large receptacle which is not divided into sections or divisions by a septum or valve of any kind. It is easily understood how under such circumstances an incipient purulent cystitis rapidly spreads to the pelvis of the kidney and to the kidney substance and will cause a pyelonephrosis.

The prostatic patient is usually first notified of his trouble by a difficulty in voiding urine. This difficulty grows as the hypertrophy increases. Some day retention of urine takes place. Symptoms of irritable bladder, frequent desire to urinate and pain, often very severe, are other concomitants. There may be a backache and tension in the region of the bladder. Even when spontaneous voiding of urine is still possible, the complete evacuation of the bladder may be impaired or interrupted from a want of power in the bladder-wall to contract. A part of the urine decomposes in the cul-de-sac, or in some pockets may become stagnant. Now, if by means of an unclean catheter or by the introduction into the bladder of some of the bacteria that always inhabit the anterior urethra, as was shown by Lustgarten and Mannaberg, the urine be decomposed, a catarrhal cystitis is soon developed. Decomposed urine causes a continual irritation and the cystitis spreads into the deeper layers of the bladder-wall, and in the presence of pyogenic bacteria we soon have a suppurative or gangrenous cystitis.

The greatest danger consists in the upward progress of the infection through the ureters to the kidneys. We often find that the infection spreads rapidly, as there is nothing to interrupt its progress from cystitis to pyelitis and nephropyelitis. Prostatics nearly all die sooner or later of pyelonephritis. The clinical picture is that of pyelonephritis and sepsis, except in some cases in which both kidneys are severely affected. In the latter event the patients die an easy death with uremic symptoms.

Suprapubic Cystotomy as a Method of Drainage in the Treatment of Hypertrophy of the Prostate; Myomectomy as a Radical Cure.—Suprapubic cystotomy is an operation which finds its application in (1) stone in the bladder, (2) tumors and growths, (3) hypertrophy of the prostate, (4) foreign bodies, (5) exploration of the bladder, and (6) drainage of the bladder.

It is a recognized and successful method of treatment in all of these conditions. The technic varies with the object in view. If it is desired to open the bladder merely for the removal of a foreign body the wound may be closed at once. If we desire to establish drainage the bladder must be kept open and a buttonhole may be established by stitching the mucosa to the skin. This fistula may be left open for weeks or months, but can be closed whenever the object of the drainage has been achieved. I will not describe the method of operating, because it is a simple trick devoid of danger in the hands of any experienced surgeon. I regard it as one of the minor surgical procedures and may assume that you will all agree to this proposition. A little reflection will show that the operation is only indicated when the bladder is full or can easily be filled with either air or water. The use of a rectal bag is unnecessary; in short, the operation is one of the simplest and easiest in all surgery. But one landmark is required, and that is the symphysis pubis behind which the bladder is always found and is easily punctured or incised with or without an intravesical guide.

I have to do with the operation to-day only in its relation to drainage as a method of treatment in prostatic hypertrophy and its most troublesome complication, cystitis.

Some ten years ago I got the notion that suprapublic drainage would cure prostatic hypertrophy. I reasoned that by the drain I could give complete physiological and mechanical rest to the bladder and that I could prevent the unrest due to the alternate filling and emptying of the bladder. We all know that Nature does its work of repair rapidly and painlessly if we can only give rest to the diseased organ; this axiom applies to all diseases without exception, including the many forms of infection. What is infection unless it be the unrest produced by microbes and their toxic products upon the tissues? Remove the toxic agents, the cells will be at rest and there will be no inflammation. The best definition of inflammation is the following: Inflammation is the response made by the tissues to toxic agents which invade them. I had often seen the mucosa of the bladder, which had become inflamed and ulcerated, return to its normal condition in a few weeks after a suprapubic section and drainage, and of course I knew that the cystitis accompanying many cases of hypertrophied prostate would disappear under the free drainage and the rest which was given the bladder by this simple operation. There can be no doubt on this point, but I had hoped that the hypertrophied prostate under the influence of rest would undergo absorption and atrophy and that a decrease in size which might be permanent would take place. In this latter hope I was doomed to disappointment.

It is true that in all cases of hypertrophy in which I made free permanent drainage for from three to ten weeks the urine became normal in color, the cystitis was much improved and in some cases entirely cured. It is also true that the enlarged prostate in each case became smaller and that the patients were exceedingly comfortable during the time that the drainage was kept up. One patient, Mr. T., who had a severe cystitis and who suffered extremely from his enlarged prostate, was so much relieved by the suprapubic drainage that his praise of the service rendered him was most grateful to my ears. "Why, just think of it! I sleep all night without getting up, do not have to use the catheter, have no temperature at bedtime and my appetite has returned." This patient died suddenly one morning as the nurse woke him; he raised himself up in bed to greet the nurse and fell over dead. In that case I was permitted to hold an autopsy and found that the prostate was quite large and that there was a large myoma in the left lateral lobe of the prostate and a small one of the size of a filbert in

the right lobe which projected across the median line. It seems clear to me now that no matter how long I might have drained this man's bladder the myomata would probably not have atrophied, and I am reasonably certain that the cystitis would have returned with the closure of the suprapubic drainhole and resumption of the catheter life. I may add that death was due to embolus and that the primary thrombus most likely came from a plugged vesical vein.

In several of my cases I had the great pleasure of seeing the prostatic hypertrophy become much reduced and remain in this condition for over a year, the patients regarding themselves as quite cured and throwing away their catheters. But I am compelled to report to you that with the exception of one man they all, twenty-six in number, were again obliged to take up the catheter life which had been abandoned for from a few weeks to fifteen months.

I am convinced that, as a radical cure of prostatic hypertrophy, suprapubic drainage is a failure. This result or conclusion might have been anticipated by reasoning from the basis of the facts which I brought out in the pathological part of my paper. It was there stated that hypertrophy of the prostate is a form of neoplasm or tumor. It is either a diffuse myomatous hypertrophy or it is a localized formation of nodular myomata, except in rare instances, which were alluded to in the first part of the paper. *Myoma in men or in women cannot be made to disappear by castration, nor can it be made to do so by giving to the parts in which it is located physiological and mechanical rest by means of suprapubic drainage.* I have had no chance to try the effect of castration and drainage simultaneously and hence cannot say what the result of this treatment would be. But there is no doubt that this treatment would be justifiable. The method must be tried. It is highly improper to condemn any rational procedure *a priori.* So long as we claim to be working upon a scientific basis, let us not condemn methods before we have tried them.

The following gives the results of my suprapubic drainage work and the fate of the patients so far as known to me: Cured, 1; leading a catheter life as before drainage, 8; operated on after Bottini and improved, 2; operated on after Bottini and not benefited, 1; operated on after Bottini and died on third day after the cautery of septic pyelonephritis, 1; operated on by perineal prostatectomy, 2 (of these one died of pyelonephritis on the fourth day after operation, the other seems to be cured); now being drained suprapubically for the second time, 1; died of pyelonephritis, senile gangrene or pneumonia, 6; disappeared and condition unknown, 4.

All of those whom I drained suprapubically were eloquent in their praises of the relief afforded to them. The patient who died of embolus was entirely relieved of his usual trouble and suffering by the drainage, and I am not sure that his death ought to count for much against the suprapubic operation. I regard suprapubic drainage as the best method of giving temporary relief to those patients who are not willing or not in condition to undergo prostatectomy. The cystitis can be cured by drainage and will not always return after the drainhole is closed. In conclusion I may say that the most rational procedure is myomectomy and that with our increasing technical experience it offers the best prospects of radically curing the evils which accompany prostatic myomata.

The word prostatectomy would indicate that the whole of the prostate is removed. This has not been the case in most of the operations that have been reported. In those cases in which the whole prostate was removed by way of perineal section, by the suprapubic route or by a combination of both methods, the mortality has been fearful. I am unable to give reliable figures because many of the total prostatectomies have been fatal without being put on record. The fact which stares us in the face in estimating the value of a new operation by statistics is that only the good results are reported and the bad ones buried. Hence statistics based on reports of a few cases by a few men are unreliable and always misleading, because they indicate a mortality which is too low.

The results of partial prostatectomy are much better as regards mortality and also in respect to functional improvement of the diseased organs. Thus, after a partial prostatectomy the mortality is very low and the function of voiding urine is preserved to a degree which is entirely satisfactory. This operation is the one which I have named myomectomy. Prostatic myomectomy is the operation which I think will be adopted very generally in the future for the radical treatment of hypertrophy. The name hypertrophy of the prostate is misleading and I would rather use the term myomatosis of the prostate. I have made sections of many specimens and parts of enlarged prostates and even in the hardest and most resistant tumors have been able to show non-striated muscle cells. I am convinced that the bundles of connective or fibrous tissue which we find in the sections are all derived from the connective tissue which accompanies the blood-vessels. This perivascular connective tissue surrounds the arteries and veins. It is known in biology as the lymph-sheath. All arteries and veins are surrounded by this lymph-sheath, which is continuous with the lymph-spaces around the capillaries. In my own sections I could prove that what fibrillary connective tissue we find is developed from the perivascular sheaths of blood-vessels entering the prostate. The principal enlargement is made up of bundles and nodes of non-striated muscular fibers which cross each other and intermingle with each other exactly as we see them in myomatous uteri. Sometimes the nodules can be easily shelled out of their beds, but oftentimes the process is very tedious and difficult. Morcellement is found to be the best way of extirpating parts of the prostatic lobes. The cases in which we find no well-defined nodules of myomatous nature, but merely an even hypertrophy of the

organ, all parts being equally enlarged, are uncommon. The nodular form is more frequently found. The number of cases I have examined is too small to permit of a more definite statement at the present writing.

In summing up my views on this subject an important and suggestive question arises in regard to the duration of catheter life. Reginald Harrison and Frank Lydston state that the average length of life of a prostatic patient after he has been initiated into the catheter life is four years. Both of these men have had a large experience and I am not inclined to doubt their statement. I know that with extreme care and under the most painstaking cleanliness, both of the person and of the catheters, two men surrounded by the luxuries of wealth have lived nine years and eleven years respectively and are in good physical condition. One of these men has had several attacks of cystitis and has passed through them successfully. The other one was operated on several years ago for a stone in the bladder by litholapaxy. My own experience would lead me to place the average length of catheter life at a longer number of years, but I am not in a position to speak authoritatively on this point. At any rate, catheter life is associated with much danger and an infection may at any time take place and even in spite of good management will often lead to pyelitis, to pyelonephritis and to death.

Knowing the dangers of catheter life and the shortcoming effect it has on the duration of life, we must deliberately decide the question as to its usefulness and we must not recommend it without great hesitation. The time when a prostatic first seeks our aid and assistance is the time when we must decide what to do. The first time a patient has retention is the time when he must either be taught to use the catheter for the purpose of drawing off the residual urine three or more times per day or the surgeon must decide to get rid of the cause of the trouble by some other means. I believe that in the long run much suffering and the unavoidable dangers to life and health which accompany prostatic hypertrophy can be spared to old men if myomectomy be performed in the beginning. The operation, if done early, before the patient's strength and recuperating powers are wasted, will be a safe one accompanied by a low death-rate. The technic of this operation known now as perineal prostatectomy I shall not describe in this paper, but I will say that the procedure has been frequently performed and is highly recommended by Bryson of St. Louis and Ferguson of Chicago. The methods which they have described and the methods of Von Dittel, Alexander, Harrison and others are before us.

My operation which I have called myomectomy does not aim to remove the whole prostate, but merely those parts of it which have impinged upon the vesical end of the urethra and have interfered with the function of the bladder in such a manner as to prevent complete evacuation of its contents. Myomectomy is a perineal partial prostatectomy and its technic is practically the same as that of the perineal prostatectomies which are now before us in recent surgical literature. The important technical point in the operation is that the connection between the mucosa of the bladder and that of the urethra must not be completely interrupted. A broad strip of mucosa should be left which connects the bladder with the urethra.

Conclusions.—In old cases of hypertrophied prostate palliative measures are sometimes preferable to radical measures.

Drainage of the bladder by the suprapubic route is preferable to perineal drainage in cases of cystitis, because the suprapubic method gives the sphincter apparatus more complete rest than the perineal buttonhole or fistula.

In recent cases of hypertrophy, in which the patient's health has not been injured by chronic cystitis or nephropyelitis, the dangers of myomectomy or perineal prostatectomy are minimal and in these cases a radical and satisfactory functional result can be achieved by myomectomy.

Operation must be regarded as a palliative measure intended to enable the patient to evacuate his bladder more completely than before. It will probably have a very limited usefulness and will be crowded out of practice as the technic of myomectomy or perineal prostatectomy is perfected.

Bottini's operation is dangerous and must not be undertaken unless most careful measurements have been made. It is often followed by extravasation of urine into the perineum and perineal section must be done in order to save the patient's life as soon as swelling of the perineum is noticed.

Myomectomy done through a median perineal incision is the operation which promises the best results and is the operation of choice. It is applicable to the greatest number of cases in which permanent cure may be expected, the kidneys being physiologically sufficient and unimpaired. The perineal fistula will always close spontaneously after the perineal drainage is discontinued, and if enough mucosa has been left there will be no stricture.

MEDICAL PROGRESS.

MEDICINE.

Incandescent Electric Light and Infectious Diseases.—Knowledge of the influence of sunlight on bacterial development first suggested investigations concerning the bactericidal power of electric light. Gebhardt and Aufrecht showed that animals infected with anthrax bacilli, pyogenic bacteria, tubercle and diphtheria bacilli and then permanently exposed to incandescent electric light resisted the infection much more successfully than did control animals similarly inoculated and not subjected to the influence of the electric light. It was as first too readily assumed that similar results could be obtained in human beings; Böder, however, showed that the rays of electric light were powerless to control acute or chronic general diseases in human subjects. Later experiments on animals by

Von Drigalsky produced evidence which contradicted that of Gebhardt and Aufrecht. KREBS (Berl. klin. Woch., Jan. 15, 1902) has reopened the question in a series of observations on mice and guinea-pigs. Mice inoculated with bouillon and agar cultures of anthrax failed to derive any benefit from exposure to electric light. Such exposure had no influence either for good or evil on guinea-pigs inoculated intraperitoneally with typhoid bacilli. Krebs concludes that there is no immediate prospect of the successful treatment of more or less acute bacilliary diseases by means of the incandescent electric light.

Diabetes and the Superheated-Air Treatment.—Diabetes mellitus is under all circumstances a most difficult disease to manage and has long since been considered practically incurable. D. WALSH (Med. Press and Circ., Jan. 15, 1902) reports a case which came under his treatment in January, 1901, with sugar in the urine amounting to 2.5 per cent. This patient underwent several courses of Tallerman's superheated-air treatment. As a result the sugar was decreased by April 15th to 0.71 per cent., and in June and July there was hardly a trace. The author makes the suggestion that this method be tried faithfully whenever available with the hope that in certain cases it may prove an active means of aiding the patient.

Bubonic Plague.—Among subhuman animals, the clinical course of the plague is very characteristic in rodents and monkeys. M. D. ZABOLOTNY (Archives des Sciences Biologiques, Vol. VIII., No. 4, 1901) while in India performed some experiments upon monkeys, as these approach so nearly the human species. He found that it was easy to produce in monkeys the two common clinical forms of the plague, the bubonic and the pneumonic, and that even after manifest symptoms of the disease a cure could be brought about by the use of Hafkine's antiplague serum. This cure in the course of plague is accompanied by phagocytosis in the buboes. Preventive injections of small doses of serum are to be preferred to large doses administered late, and immunity is only obtained by repeated small doses. The injection of the toxins and dead cultures of the bacteria was always accompanied by a marked leucocytosis.

Pancreatic Disease.—Diseases of the pancreas are as rare as they are interesting. DR. MURRAY of Cornell (Amer. Med., Jan. 25, 1902) reports three cases which do not, indeed, go very far to clear up the present obscurity of the subject, although they illustrate the possible sources of error in diagnosis. Of these, the most common are cholecystitis, perforation of the gut, and appendicitis. Murray believes that the most important symptoms are the presence of fat and proteids in the stools and of sugar in the urine, especially in the absence of jaundice and of intestinal disease, and the existence of tumor in the epigastric region. He says that whenever one meets with a case of acute epigastric peritonitis in which the etiology is obscure, pancreatitis should be suspected, and if the patient's condition admits of operation an early abdominal exploration should be made. Surgical intervention seems at present to offer the only possible mode of relief for this class of cases, although its exact methods and scope have not, unfortunately, been determined.

Acute Streptococcus Pharyngitis.—In four cases which occurred at one time in his practice, suggesting an epidemic, L. S. SOMERS (Medicine, Jan., 1902) found the same kind of bacteria, the same run of fever and bilious symptoms, and the same rapid disappearance of the membrane and all the symptoms except a feeling of severe exhaustion which depressed the patients for several days. The first thing to do is to determine whether or not the disease is diphtheria; a limited area of membrane formation or even entire absence of membrane does not rule out a Klebs-Loeffler infection. The usual streptococcic angina is very severe, but these cases were mild and closely resembled diphtheria. All the cases gave a history of previous catarrh. In no case did the infection occur twice in the same family or house. In some patients localized areas of epithelial necrosis, or herpetic pharyngitis after the vesicles have ruptured cannot be distinguished by the naked eye from false membrane. This is also slightly true of leucoplasia, mycosis and some of the aspects of syphilis. The small round epithelial plaques sometimes seen in influenza occasionally assume a membranous aspect, but they are limited in extent and do not tend to encroach on neighboring areas.

Nature of Typhoid Fever.—It has been evident for some time that the conceptions of the last thirty years with regard to the nature of typhoid fever would have to be modified. With the perfection of bacteriological methods, it has become more and more frequent to find authentic cases in which the intestinal symptoms, or at autopsy the intestinal lesions, have been subordinate or entirely lacking, while some other organ of the body has constituted the theater of disease. Such cases, with no bowel lesions, have been variously described as pleurotyphoid, pneumotyphoid, arthotyphoid, in brief, as abenteric typhoids. The typhoid lesions of the intestine would seem, therefore, to take their place with those of the other viscera, as merely secondary and local expressions of a general infection. The site of primary invasion still remains to be determined, and it is to this problem that EUGENE WASDIN (Amer. Med., Feb. 8, 1902) has devoted a very suggestive article. He asserts that in every case of typhoid he has been able to identify an area of lung presenting rather peculiar and characteristic signs. "On percussion the resonance is diminished, the note being higher. Auscultation will always give evidence of impaired vesicular breathing, a paresis. With these symptoms there are bronchial breathing, mucous and sibilant râles, and cough." The condition is usually unilateral, the lower lobes being most frequently involved. Expectoration is scanty and may be blood-stained. Pathologically, the condition is a typical hemorrhagic edema, both interstitial and alveolar. The bacteriological examination of the sputum is, unfortunately, not very illuminating. The physical signs are very evidently not those of an ordinary bronchitis, or of hypostatic congestion, and Wasdin regards the pulmonary foci as the primary colonizations of the typhoid germs. Thence they pass into the blood current, giving rise to the multitudinous symptoms characterized as septic or toxic, and with the aid of proper bacteriological precautions they may now be isolated from the blood. Finally, they become localized again in various tissues and organs of the body, either through an especial vulnerability of the affected structures or because the toxins have previously prepared the way for their invasion. Among such "terminal" expressions of the disease are to be reckoned the roseola, the intestinal ulcers, typhoid joints, and so forth. It will be seen that this theory, though apparently revolutionary in character, merely modifies the site of primary invasion, not the nature of the disease itself. It is certainly interesting and suggestive, but it can never find acceptance upon the basis of purely clinical evidence. Bacteriological demonstration must remain the final criterion and the only adequate proof of the primary localization of the disease.

Atonic Dyspepsia.—By atonic dyspepsia is meant the gastric derangement which results primarily from deficient activity on the parts of the muscular coats of the stomach. It is a disease which has received especial

attention from English clinicians, whose views on the subject are very conservatively presented. Wm. Carter (Birm. Med. Rev., Jan., 1902) recognizes two types, namely, atony with stagnation, in which the stomach fails to empty itself within the four to five hours intervening between two successive meals, but becomes empty overnight, and atony with retention, in which the stomach never empties itself. The disease may be secondary to nervous or secretory disorders of the stomach or to pyloric obstruction, in which case its significance is entirely subordinate. When it is the primary disorder, it is traceable etiologically to two groups of causes, namely, those acting directly on the stomach, such as excess in drinking and eating, hurried meals, large drinks between meals, and so on, and, secondly, to those acting indirectly by lowering of the general health and nutrition. With regard to the recognition of motor insufficiency, Carter asserts that Chomel's sign, gastric succussion, is by far the most generally useful. In obtaining it, one should see that the abdominal wall is thoroughly relaxed, and the shock transmitted by the fingers should be suddenly produced and strictly vertical in direction. When positive, it invariably indicates the presence of fluids in the stomach. It may be confirmed by the use of the stomach-tube, and by the salol test of Ewald. The grade of muscular paresis present is, of course, indicated by the length of time after the preceding meal during which succussion is still elicitable. The associated atonic dilatation, or gastroptosis, is revealed by the altered contour of the abdomen, by observation of the area over which succussion may be induced, and, if necessary, by inflation of the stomach. In the treatment of the milder grades, the chief indications in the way of diet are to avoid overdistention. One may either give small meals at shorter intervals than usual, a plan which is advisable when the appetite is poor, or one may give carefully selected but substantial meals at longer intervals than usual. With regard to the character of the food the two most important rules are: (1) Reduction of fluid taken with food to a minimum; and (2) the selection of a mixed diet, consisting of compact nutritious food. Fermentable foods are to be avoided. Drinks are to be taken when the stomach is empty, as on arising, or at bedtime. The most useful drug is strychnine; the best aperient, aloes or cascara. In atony with retention, it is best to put the patient to bed for a week or so. The dietary indications are those already outlined. In most cases, lavage of the stomach is essential for really good results and should be practised in the morning. Warm water, containing a dram of boric acid and from 15 to 20 grains of salicylic acid to the pint is the best medium. Bismuth, sulphocarbolate of soda, and resorcin may also be used.

Cure of Consumption.—The late British Congress on Tuberculosis has been most fruitful in important recommendations for treating the disease. B. H. Steede (Med. Press and Circ., Jan. 8, 1902) discusses the value of sanatoria for the isolation and treatment of these patients. These institutions have already proven their value beyond dispute. They are a great help, partly by the cures certainly effected, partly by the isolation for the time of the cases, and finally and chiefly by the knowledge they spread of the nature of the disease, of the measures necessary to avoid infection. There are, however, patients who are not suitable for treatment in sanatoria and the care of these is most important. By their circumstances and their habits they spread the infection more than all others. They should therefore be lodged in special institutions and their houses disinfected. Homes for the incurable consumptive poor are the most pressing necessity. In considering the mortality of tuberculosis the need of such institutions has, of course, been felt ever since the infectious nature of the disease was established. Latterly the practicability of these institutions has been considered. Dr. Ring, of the State Government of Michigan, a delegate to the Congress on Tuberculosis, read a paper as to the family history of 242 cases. He thinks that parents with consumption tend to confer immunity rather than predisposition to consumption in their children. The public are generally convinced, however, that the disease is hereditary. The point is by no means settled and the chances are all on the negative side of the question. What the public must now believe is that it is a disease which is liable to attack successive inmates of the same house rather than successive members of the same family unless they are all living together. Coates of Manchester has recently carried out similar investigations with these conclusions as to the dust taken from three classes of houses. He found tubercle bacilli in the dust of dirty houses inhabited by consumptives who took no care whatever with regard to the disposal of sputum, etc.; he found the tubercle bacilli in the dust from houses which were apparently clean and well kept, but which were inhabited by consumptives who took no proper precautions; he found no tubercle bacilli in the dust from very dirty houses which were known not to have been inhabited by consumptives for several years. In France an institution has been founded called the Antituberculous Dispensary. It has been established for several years and endeavors to give the best possible medical service in the homes of all tuberculous patients whose necessary cessation from work would condemn them to utter distress. The consumptive poor must receive help in some form or other from the community. This dispensary systematizes, directs and increases the help given by private or public benevolence; sees that the danger from infection is minimized; provides good food and gives aid as far as the funds allow; and improves the surroundings of the patient so as to benefit him and protect his friends.

Serumtherapy in Acute Rheumatism.—In a case of acute articular rheumatism involving the wrists, elbows, knees and ankles and characterized by chills and a very irregular temperature, suggesting a pyemic condition, R. J. Chipman (Med. Rec., Feb. 1, 1902) used salicylates, opiates and local fomentations without benefit, the patient's condition after two weeks becoming very serious. The chills were followed by high temperatures, 104° to 105° F., and profuse sweats. The cardiac action became rapid and weak. Three injections of ten cubic centimeters of the antistreptococcic serum were made and both the general and local symptoms rapidly improved, although the patient seemed previously to be in a dying condition.

Cause of Dengue.—Since the mosquito has been found to be the medium by which malaria and yellow fever are transmitted from one patient to another, this little insect has been suspected of being instrumental in propagating several other diseases. In the study of dengue in Beyrouth, Syria, H. Graham (Med. Rec., Feb. 8, 1902) found that if the patient sick with the disease was kept in a room free from mosquitoes there was no danger of communicating the disease to others. Literature shows that for many years certain miasmatic influences were thought to be required for the propagation of the disease. In the further investigation of the etiology of dengue, experiments in inoculation were made and when persons were exposed to the bites of mosquitoes that had previously bitten dengue victims, these persons in time developed typical attacks of the disease in from four to six days. Furthermore, infected mosquitoes were taken to a mountain town where dengue seldom appeared and two healthy boys exposed

themselves to their bites. One developed an attack of the malady in four days and the other in six days. The blood of various patients was then closely studied and more positive proof of the cause of the disease discovered. A plasmodium similar to that of malaria, but differing from it in many essential characteristics, was found in over 100 cases. This plasmodium had a much slower development than that of malaria, so that fresh specimens would not last long enough to trace the development very far. They grow within the red blood-cells, at times sending out pseudopodia and on the fifth or sixth day the corpuscle is broken up and the plasmodium seems to degenerate. No pigment is formed within the protozoon at any time. In several cases presenting severe second or third attacks flagella were seen in the blood showing a distinct undulatory movement by which they progress, some of them having clubbed ends. Although the cycle development has not yet been followed through the mosquito there seems to be little doubt but what dengue also will be proven to be communicated only by this insect.

Yellow Fever and the Mosquito.—The theory, recently promulgated and based upon work done in Havana, that the mosquito plays as important a rôle in yellow fever as in malaria is strongly opposed by J. P. Oliver (Texas Med. Jour., Jan., 1902), who finds that the evidence that the disease is introduced into towns by goods or merchandise packed in boxes or trunks, or by persons in whom the disease is incubating and develops after arrival, is so overwhelming that it is not necessary to draw in the mosquito as intermediary host. Accepting the mosquito theory, it is hard to understand where the insect gets its poison with which to inoculate its first case and to explain those cases cited in which a strict quarantine was maintained and no yellow fever appeared until this quarantine was broken, despite the fact that the mosquito was abundantly present and had free access to those afflicted. Examples are also cited in which sickness could be directly traced to certain infected articles, and these facts render the mosquito theory altogether untenable.

Echinococcus Disease in North America.—A very interesting review of over 200 cases of echinococcus disease observed in this country is given by I. P. Lyon (Virg. Med. Semimonthly, Jan. 10, 1902). He finds that 74 per cent. of all the cases occur in young and middle-aged adults and that under ten years the disease is a rarity, in spite of the fact that young children are apparently most exposed to the infection. The disease is also rare after the age of sixty. The proportion of males to females is 3 to 2. Forty per cent. of the cases were Icelanders living chiefly in Manitoba; Germany shows 15 per cent., Italy 14 and Great Britain 9 per cent., while those of native birth also amounted to 9 per cent. The relative immunity of Americans is seen even among the American-born children of the Icelandic immigrants. The disease prevails chiefly in the lower classes, particularly among the ignorant and slovenly. The State of New York furnishes one-quarter, Canada one-third of all reported cases, and it is noticeable that few are found in the Western States, where it would seem that conditions favorable for the spread of the disease exist. The liver was found involved in 73.7 per cent. of the cases; next to this organ the order of frequency is as follows: Omentum and mesentery, lungs, spleen, kidney and bladder. Some unusual localities were found, such as hernial sac, nasal septum, pericardium, head of humerus, brain, eye, prostate, testicle, pancreas and pleura. In only four cases was the multilocular type noted. The diagnosis seems to have been based upon the gross appearance, the site and the presence of daughter cysts. The important question, if the disease is increasing, cannot be answered authoritatively at present, since the statistics are of too recent years. Statistics of animals show great variations, but it is quite likely that the disease is not evenly distributed and that endemic foci exist. Concerning prophylaxis it may be said that the disease can be exterminated by enforcing proper sanitary regulations at the slaughter-houses and by guarding against too intimate intercourse between dog and man.

Turbid Urine in Eclampsia.—In two cases of eclampsia and one of uremia, all three ending fatally, H. Cramer (Münch. med. Woch., Jan. 21, 1902) found a peculiar milky urine voided, suggestive of chyluria. The close chemical and microscopical examination, however, showed that the milkiness was due to innumerable suspended particles, albuminous in nature. Since in all three cases very much albumin was present on boiling, it is possible that the strange phenomenon was due to a supersaturation with albumin, especially since the urine cleared up upon sufficient addition of water. It is also possible that the suspended albumin is of a different nature than the dissolved albumin. From a prognostic point it seems that death is not far off when the emulsion is voided.

A New Theory of Diphtheria.—A good deal of difficulty has always been experienced in sharply differentiating true and pseudodiphtheria bacilli on a morphological basis, and F. Schanz (Münch. med. Woch., Jan. 14, 1902) is of the opinion that their only difference lies in their power to produce toxins. It has been found, however, that the blood of most people contains a certain amount of antitoxin which may result from a previous diphtheria, but may also come from the harboring of a virulent diphtheria bacillus, which strangely does not lack in antitoxin-producing properties, on the mucous membranes of the nose or other organs. The degree of severity of a diphtheria may thus depend on the amount of unconscious immunization which has constantly been going on from a virulent bacillus.

THERAPEUTIC HINTS.

Rheumatismal Pleurisy in Children.—

℞ Sodii salicylat..... 3.0 (gr. xlv)
Syrupi .....30.0 (℥i)
Aquæ .....75.0 (℥iiss)

A tablespoonful every two hours for a child of six years. Gram 0.50 (gr. viii) of salicylate should be given each day for each year of age.—Comb in Le Progrès Médical, Jan. 18, 1902.

Adulteration of Drugs.—After examining numerous samples, L. F. Kebler (Amer. Jour. of Pharmacy, Jan., 1902) reports as follows: Acetamide, which keeps better, is often sold for ammonium acetate; precipitated calcium phosphate contains up to 30 per cent. of calcium carbonate; chromic acid may contain 60 per cent. of acid sodium sulphate; powdered podophyllum may be sold for podophyllin; vanillin may contain up to 90 per cent. of benzoic acid, or 50 per cent. of acetanilid; oil of cassia is adulterated with kerosene; the oils of peppermint and thyme with oil of turpentine; balsam of copaiba with gurjun balsam; aconite root with tormentilla; extract of lettuce is substituted for lactucarium; inferior aloes for the official article; inferior gums for acacia and tragacanth. Gross adulterations are very little practised at present, detection requiring the use of test-tube, analytical balance, microscope or polariscope.

The Eye in Variola.—Almost any eye condition may complicate smallpox, but practically the only one that is likely to lead to blindness is a pustule or abscess of the cornea. M. Dufour (Revue Médicale de la Suisse Romande) has had great success in treat-

ing such a condition by the subconjunctival injection of a 1-2,000 solution of mercuric bichloride, repeated at three day intervals. Hypopyon disappears, the opalescence of the cornea clears away, and the site of the abscess tends to cicitrization.

Arsenic in Tuberculosis.—This drug is especially advantageous in the early stages of tuberculosis, and in the chloro-anemic forms common in young women. Preference is given to its employment hypodermatically, a solution of 5-10 centigrams to the cubic centimeter being administered once daily. By mouth it may be given in concentrated solution, containing 1 centigram to 5 drops:

Cacodylate of soda.....	0.40	(gr. vij)
Distilled water	10.00	(ʒ iiss)

Or in pill form:

Cacodylate of soda.....	0.025	(gr. ⅓)
Extract of gentian.....	10.000	(ʒ iiss)

For one pill.

It may also be administered by rectum:

Cacodylate of soda.....	0.40	(gr. vij)
Distilled water 200.00		(ʒ vj)

Inject 5 c.c. in rectum twice daily.

The treatment should be intermittent, however administered; generally hypodermic injections are given once daily for eight days, and suspended for eight days; or injections may be given two or three times weekly.—Jour. d. Méd. d. Paris, Jan. 12, 1902.

Pessaries versus Operations.—The general practitioner too often tells his patients that a major operation is necessary for some displacement. When a woman has been told that she needs an operation, she rarely rests easy until it has been performed. The measures required to hold the uterus in its normal position are as follows: Hygienic regulation of food, dress and evacuations, massage for stimulation of the parts and relief of congestion; local and general treatment for the reduction of congestion and inflammation; the use of pessaries, or operation. Tenderness from inflammation, adhesions, cicatricial bands, the weight of a large tumor or relaxed pelvic floor may contraindicate the use of a pessary. Therefore the pessary, as a rule, can only be used when the displaced organs are replaceable or can be made so, and when the pessary is efficient in holding them in place and can be worn without discomfort. The use of the pessary depends on the rule that if the cervix is normally placed, the body of the uterus will take care of itself. A suitable pessary should allow the patient to ride, jump, dance and carry on the marital relation. When the displacement is due to inflammation this must be reduced by local treatment before the pessary is adjusted. If the inflammation is due to the displacement, the pessary may relieve all the trouble. While a pessary is worn the patient should use cleansing douches of a quart or two of hot water daily, and every month or two should be cared for by the physician. Repair of lacerations of cervix and perineum may aid. Round ligament operations are often of only temporary benefit. Ventral fixation may cause as much discomfort as the displacement has caused intestinal obstruction, and may interfere with pregnancy reaching full term.—G. W. Kaan in Annals of Gynecology and Pediatry, Dec., 1901.

Puerperal Septicemia.—It is common to see patients, writes F. A. Higgins (Annals of Gynecology and Pediatry, Dec., 1901) with symptoms of impending septicemia following abortion, with a temperature of 103° to 105° F., pulse 120 to 130, uterine tenderness and foul discharge, who after complete curettage with antiseptic douching and regular régime, return to normal conditions in from one to three days. Such cases have not reached the stage of general septicemia and the infection is removed by local treatment. Of 38 cases of profound septicemia at the Boston City Hospital, 11 followed abortion and 27 followed labor. Sixteen died. The most important complications were septic pneumonia, endocarditis, mania, phlegmasia dolens and purpura. Antistreptococcus serum was administered to five patients, only one of whom recovered. The serum seemed to have a very depressant effect. Fresh lacerations of the cervix were very common among the infected women and the writer believes these the avenues for germ entrance. There is no routine treatment, but if the uterus remains large and soft, if there are retained products, and if there is a profuse foul uterine discharge, curettage will remove the focus of the disease and promote involution. If there are no retained products and the uterus is firmly contracted, curettage is useless. Following curettage weak antiseptic intra-uterine douches of bichloride, normal saline solution, or formalin, one-half to one per cent., have given good results.

Acute Bronchitis.—

℞ Tinct. scillæ.....	0.7	(♏x)
Syr. codeinæ.....	20.0	(ʒv)
Extract. hyoscyami.....	0.05	(gr. i)
Aq. aurantii florum.....	10.0	(ʒiiss)
Julep 120.0		(ʒiv)

Dose: One dessertspoonful.—G. Lyon in Le Progrès Médical, Jan. 11, 1902.

Non-diphtheritic Membranous Angina.—Gauchez recommends the local application of

℞ Camphoræ 20.0		(ʒv)
Ol. ricini.....15.0		(ʒiv)
Alcohol 10.0		(ʒiiss)
Ac. carbol. cryst.....	5.0	(gr. lxxv)
Ac. tartarici.....	1.0	(gr. xv).

Dropsy.—In general dropsy from heart or kidney disease, Shoemaker considers the following valuable:

℞ Potass. bitart.....	15.5	(ʒss)
Extr. convallariæ fl.....	6.0	(ʒiss)
Syr. simplicis, q.s. ad.....120.0		(ʒiv)

Indigestion.—A good preparation in chronic hepatic derangements, especially of malarial origin, and for sick headache depending on indigestion is as follows:

℞ Ext. iridis fl.,		
Ext. hydrastis fl., aa.....15.0		(ʒss)
Elix. aromat.....30.		(ʒi)

Dose: A dessertspoonful in hot water before meals.

Respiratory Failure from Anesthetics.—First remove any possible obstruction to the breathing, open lips by finger or mouth-gag, and get lower jaw forward till the lower teeth are in front of the upper. It is a common mistake for the beginner not to place his fingers really behind the angle of the jaw, but on the lower surface, so that pressure does not push the jaw forward. Keep the tongue forward and make sure that it is not caught in the teeth. If necessary catch the tongue and pull it well forward, but do not keep forceps tight on the tongue for any length of time, as they will injure it. If the tongue has to be kept forward, better pass a ligature through it instead of using forceps. Rubbing the lips briskly with a towel or the application of ammonia to the nostrils is often sufficient to reestablish breathing. If the corneal reflex is present give more anesthetic; if absent, give more air. If the obstruction to breathing seems due to mucus, the pharynx should be cleared out with a sponge on a holder and the anesthetic changed to chloroform or the A. C. E. mixture. In an extremity, rhythmic traction of the tongue may be effective. If these means are of no avail, artificial respiration must be promptly resorted to. The one drug that may be given is strychnine hypodermatically.—Probin-Williams in "Administration of Anesthetics."

SATURDAY, FEBRUARY 22, 1902.

THE SMALLPOX VERSUS DR. PFEIFFER.

A smallpox case destined to be famous in the history of the progressive victory of therapeutic science over the ranks of ignorance, prejudice, quackery, and sentimentalism, is that of Immanuel Pfeiffer, M.D., of Boston and of Bedford, Massachusetts. This physician was certainly one of the most vigorous and intelligent of the antivaccinationists, yet he was very certain, in his own mind, that smallpox is not a contagious disease, but that it is rather the product of bad hygiene and evil diathesis. This belief in the mind of a medical man properly ratable as of average intelligence is in itself a striking illustration of a wise and ancient proverb—"There are none so blind as those who won't see"; and at the same time it is a notable index of the status of the "antis" in general—"agin the gov'ment," whatever its complexion, dissatisfied with the actual order of events, with "things as they are."

Dr. Pfeiffer has been for many years emphatic in his denunciation of vaccination. He deemed it always an injury and never a benefit, but he denounced it especially because he considered compulsory vaccination a violation of the rights of the individual, however strikingly oblivious such "rights" may be of the undoubted rights of others, far more numerous, in their demand to be protected by the State from all preventable disease.

Dr. Pfeiffer, to his honor be it said, had the courage of his convictions on this subject, and in this respect at least he differed from the great majority of his cult. During a recent antivaccinational hearing before a committee of the Massachusetts Legislature he undoubtedly determined to prove that to a person in vigorous health, as he himself then was, smallpox is not a contagious disease. This fact he hoped to demonstrate and he chose the means best adapted certainly to make his expected demonstration publicly emphatic. To obtain permission from the Boston Board of Health to visit the numerous patients in the city's smallpox hospital on Gallop's Island was for him, as for other physicians, a comparatively easy matter, and Dr. Samuel H. Durgin, Chairman of the Board, showed at once his wisdom and his scientific foresight by allowing Dr. Pfeiffer to make this visit unvaccinated, although of course against the rules. Criticized for this exception in the light of the event, Dr. Durgin has ably defended himself on the one principle which is valid always and everywhere, the principle of Utilitarianism, of the greatest good to the greatest number. Rather than be vaccinated, Dr. Pfeiffer unquestionably would have stayed away, and an experiment of great practical value to the world would have been missed. But, to indicate an example of the questionable and often deceitful means in the employ of the antivaccinationists, let us rehearse the reasons given by the Doctor for desiring permission to make this visit, remembering that at the very time he was publicly urging the non-contagiousness of this disease, but with adequate evidence lacking. To the Chairman of the Board of Health he wrote:

"Referring to our conversation of recent date, and your request to my representative that I write you a letter asking for permission to visit the smallpox hospital at Gallop's Island, for the purpose of scientifically looking into the disease in all its various forms, and with close observation be able to get such facts, which will enable a physician to diagnose smallpox cases with as much certainty as possible, and also to get the facts in regard to the most successful treatment, I would say that I have already considerable experience, gathered in Europe, and am anxious to increase my knowledge."

On this representation the permission was readily granted, and on January 23d, well escorted by officials of the Board, he visited the Hospital. He thoroughly examined the institution, and went to the bedsides of many of the patients, and he took all the precautions which other visitors take to avoid infection (such as the

wearing of a close-bound gown and cap, washing the hands, beard, hair, etc., on leaving), save that of vaccination.

For the next ten days, more or less unknown to himself, he was watched and attended by physicians from the Board of Health in order that the public might be protected from infection from his anticipated disease. During these ten days he was at his office and in the antivaccination hearings as was his wont. But on February 3d, ten days after his visit to the Hospital, when the officer called at his professional office on Washington Street, Dr. Pfeiffer was not to be found, nor did he appear at the State House hearing. In answer to inquiries his assistant stated that he was "out of the State" and he volunteered the information that he had seen the Doctor in Philadelphia on the previous day; one of Dr. Pfeiffer's clerks said that she had received a letter from him on January 27th having on it the New York City postmark. The presumption certainly was to any one unfamiliar with antivaccinational methods that Dr. Pfeiffer had been and still was "out of the State." Naturally enough, the Board of Health suspected him to be much nearer home than New York and they even feared that he might be coming down with smallpox. Soon it became known that he had been seen about Charlestown, a part of Boston, but at his office it was denied. This denial was made by a woman clerk in Dr. Pfeiffer's office, yet within an hour thereafter this same woman, accompanied by a doctor, descended a back stairway to a narrow alley, and so reached a side street and a closed carriage that was there in waiting. This carriage, it was learned, conveyed its occupants to the office of a physician on Chambers Street; and there the positive information of the Health Board ended. This physician has since, it is understood, denied that he had any such patient. This was on Thursday, February 6th.

On the following Saturday, fifteen days after the visit to Gallop's Island, the Boston Board of Health received notice from a physician that Dr. Pfeiffer was ill at his home in Bedford with what was probably smallpox, and asking expert diagnosis, the case having been reported by Dr. Pfeiffer's son to the Selectmen of that town. Experts went at once to Bedford and found Dr. Pfeiffer suffering from a very bad attack of the disease. The patient's wife stated that he had arrived home on Thursday night in a carriage saying he thought he had the grip, but his son said that the Doctor had come home on Friday night directly from New York. The patient himself was too ill to make explanations and to set right this strange and unaccountable discrepancy as regards his movements.

This is an outline of this interesting series of events up to this date. Had Dr. Pfeiffer employed all his energy in advocating skilfully, instead of opposing, vaccination, he could have had influence only insignificant in comparison with that which his grave plight has had and will have upon the public. Nothing instructs the average man, especially in masses, so easily and so effectually as an object-lesson, and here is a demonstration arranged to instruct as a medical lecturer sets up an apparatus in the amphitheater. As a prominent Health Board official said to the writer, "This is a case in a hundred years for the cause of the prevention of smallpox." That the people of Boston have benefited from this lesson is already seen in the difference in the welcome accorded the 150 vaccinating physicians now at work in the West End of Boston. But the influence of the dangerous experiment made by Dr. Pfeiffer will, it is hoped, extend wherever its lesson is needed.

The latest news from the bedside of this for once useful antivaccinationist is that he may recover, although he is suffering from the confluent type of the disease. All hope that such will be the case. In the event that his wretched malady leaves him alive, we may perhaps expect from him one of three things—either that he will deny that his disease was smallpox, or that he will relinquish his public opposition to a world of demonstrated medical wisdom; or that he will admit that smallpox *is* contagious and that the public therefore needs protection from its awful ravages by any and every feasible means.

MEDICAL RECONCILIATION.

The recent appointment by the Medical Council of the New York State Medical Association of a committee to meet the committee of conference selected by the president of the Medical Society of the State of New York at its annual meeting in January forms the next step in the process of reconciliation of the two organizations which at present divide the allegiance of New York's regular physicians. There are now ten men, all of whom are known to have the best interests of the medical profession of this State at heart, on whose shoulders rests the responsibility for the bringing about of reconciliation.

We have already pointed out how much influence and dignity the medical men of this State lose by disunion and how eminently desirable from motives of professional and public welfare reunion would prove. There is no doubt that at least 95 per cent. of the profession in this State agree with these sentiments and we must conclude that we are on the eve of reconciliation.

The recent meeting in Albany showed how much interest the practitioners of this State generally take in the old Society that has so long been representative of their best interests. Here in New York City we realize how much the State Medical Association has gained in numbers and influence in recent years. Things have come to a pass where union is possible without loss of dignity or exercise of condescension on either side. We realize that there are many difficulties yet to be overcome. Most of these are purely personal and must be put aside to make way for professional welfare. Many technical difficulties can be raised if the members of the committees of conference approach the matter in merely formal manner. The committees must understand that the eyes not alone of the profession of this State, but of most of the medical men of the country, are watching the results of the conference and the methods that may be employed to further or hinder harmony. No member of these committees will be deemed worthy of such honors as may be in the gift of the medical profession itself if they now betray the interests of medical organization by insisting too much on merely personal or partisan grounds on inadequate reasons for keeping the Society and Association apart.

No better time for reunion than the present could be found. The annual meeting at Saratoga of the American Medical Association should find a united medical profession from New York State to greet the visitors from other States. If this can be accomplished, and there seems no good reason why it should not be, since all are agreed as to its desirability, we venture to say that this year's meeting of the National Association will be one of the most notable events in its history.

The return of the Medical Society of the State of New York to the fold from which it has been absent not entirely through its own fault would be the initiation beyond doubt of an era of even greater dignity and influence than before for the American Medical Association. Everything possible should be done to bring it about.

REMUNERATION IN THE PRESIDENT'S CASE.

We are led to believe that the question of remuneration for the surgical and medical attendants of our late President is at present pending in Congress. That it is a national duty to pay the bills in the case is clear. The President while engaged in his duties was stricken down by one who aimed not at him personally, but in some blind way at government through him. It would be eminently wrong therefore to think of the services rendered to the late President McKinley as in any way personal.

Our national reputation is on trial before the world as regards our appreciation of the life of our chief magistrate in hours of danger. On the action of Congress depends what other nations shall think of us in an affair of national importance.

Republics are said to be ungrateful and not without reason, since it is the almost invariable lesson of history that services rendered by citizens to republican governments were never properly rewarded. Many other things were said of republics that have been belied by our own great republic. It remains for us to see that the blot of republican ingratitude shall no longer hold good and our legislators are in the presence of an occasion for the exercise of such generosity as will stamp our governmental dealings with citizens with the ineffaceable mark of appropriateness.

There are many good reasons why the surgeons in charge of the late President's case should be compensated with the utmost liberality. The responsibility assumed was extremely weighty. The unfortunate termination of the case does not lessen the moral responsibility of the national government to provide due compensation for this. If the autopsy had revealed that any mistake had been made the professional reputations of those in immediate charge would probably have been ruined forever. The surgeons in attendance literally staked their future careers upon the exercise of their judgment and professional skill under the distressing and inconvenient circumstances in which they were placed. The surgeons in attendance on President Garfield were treated with scant courtesy and miserly consideration unbefitting a great nation. If it were not inconsonant with true patriotism great surgeons would have felt the necessity for refusing to have anything to do with cases of national importance thereafter. The old disgrace must be wiped out. The opportunity to do

so is in the hands of the committee of the national legislature that has in charge the question of compensation of the President's physicians. Let us hope that this great occasion will not be neglected.

HUMAN AND BOVINE TUBERCULOSIS.

In the midst of the excitement aroused by Koch's declaration last August as to the absolute distinction between these two types of disease, human and bovine tuberculosis, it was a little lost sight of that the medical world owed the first real scientific work on this subject to an American, Dr. Theobald Smith. Dr. Smith's paper in the discussion that was opened by Dr. Janeway at the first December meeting of the New York Academy of Medicine represents the contribution of an original worker in the bacteriology of the subject. We are glad to be able to present to our readers the full text of the papers of Dr. Smith and Dr. Janeway. They are illuminative, informing documents on an important and at the present moment very practically interesting subject.

Dr. Smith insists on the fact that what we need in the present difference of opinion is not more theorizing and asseveration, but careful observation and patient investigation. As our knowledge of bacteriology advances nothing becomes clearer than that we cannot argue from the susceptibility of one animal to a bacillus to the susceptibility of other animals, even though they may bear certain resemblances to the first kind. No *a priori* rules will guide us as to the animal species that are liable to be affected by any given bacillus. There is, for instance, a bacillus not unlike the bacillus of fowl cholera that produces a choleraic disease in geese. Surprisingly enough, however, it does not produce the symptoms of fowl cholera in fowls other than geese and it proves to be pathogenic for rabbits. There is a micro-organism that causes an epizootic among buffaloes yet fails to affect any ordinary cattle. The size of an animal has little or nothing to do with its specific immunity to certain bacilli. Bovine tubercle bacilli are very virulent for many kinds of animals. They even prove rapidly fatal to swine, yet they fail to affect mice.

With regard to bovine, human and avian tuberculosis, more experimental work is needed before conclusions of value can be reached. There is some evidence of the transfer of bovine bacilli to human beings. In certain cases bacilli having the characteristics of bovine tubercle bacilli have been isolated from human tissues. Curiously enough, one of the most suspicious cases of this kind was reported by an experimenter working under Prof. Koch's direction, though Koch himself in his discussion of the subject makes no mention of it. It seems clear, then, that the flooding of the human digestive tract with bovine tubercle bacilli, especially in delicate early life, may be a source of serious danger. Careful precautions should be taken against any such possibility. In the present state of uncertainty this is the only safe course despite Prof. Koch's almost positive assurance of absence of danger.

Dr. Smith is of the opinion that the only way in which the vexed question of bovine tubercle bacilli being pathogenic for man can be decided is to find bacilli having the positive characteristics of bovine tubercle bacilli in the lesions of human tuberculosis. Inoculation experiments have many uncertainties. This mode of entrance into the tissues does not seem to favor the growth of bacilli that have grown accustomed to the cellular environment of a different animal species. Some preparation other than the sudden introduction into the tissues seems necessary to ensure bacillary growth. Some preliminary modification in the introduced bacilli is needed to fit them for their new surroundings. The problem is one that lies at the very base of many as yet obscure biological principles, but the outlook for its solution is hopeful in the midst of the widespread interest that has been aroused.

In the meantime the warning note uttered by so acute and conservative a clinical observer as Dr. Jacobi at the same meeting must be dominant for medical harmony in practice. The dangers from inoculation with bovine tuberculosis are too serious, if true, to be neglected because their existence is doubted by the laboratory workers. The prevention of tuberculosis in cattle and the constant inspection of the sources of our cities' milk supply is no mere agricultural question, as has been stated, but must certainly be considered a very serious necessity for human sanitation. While we may not go so far as to be frightened by the English statistics of the frequent occurrence of primary intestinal tuberculosis, there seems no good reason to doubt that sometimes there is direct tuberculous inoculation through the digestive tract. It is much better to be sure than to be sorry and none of our present elaborate system of milk inspection, in so far as it is effective, should be relaxed in the slightest degree until we have more positive knowledge with regard

to the innocuousness of infected milk. In this matter our careful scientific observers here in America have furnished us with data that enable us to draw conclusions as to our own conditions without the need of consulting foreign opinions or statistics. Our only justifiable course is to follow the practical conclusions of our own trustworthy workers.

ECHOES AND NEWS.

NEW YORK.

Positions at Pathological Institute.—Civil-service examinations will be held in New York City, March 15, 1902, for the following positions in the reorganized Pathological Institute: Associate in chemistry ($1,800); associate in clinical psychiatry ($1,200); chief associate in neuropathology ($1,800). Dr. Meyer has appointed Dr. P. H. Levene at the head of the chemical department and Dr. Harlow Brooks as associate in bacteriology.

Consulting Ophthalmologist to City Hospital.—Dr. Joseph H. Andrews has been appointed consulting ophthalmologist to the City Hospital. Dr. Andrews has served on the staff for fifteen years, faithfully and well, and the new commissioner, Mr. Folks, shows his sense of the fitness of things in making this appointment.

Work of the Montefiore Home.—The Montefiore Home, which comprises a hospital for chronic invalids and a country sanitarium for consumptives, has just made public the work done during the seventeenth year of its existence. The two institutions have provided for 280 men and 143 women. Of these 339 were inmates of the homes at the end of the fiscal year. The number of pay patients during the year was fifteen. The whole number of patients treated during the year was 737. The officers of the society at present are Jacob H. Schiff, President; L. G. Bloomingdale, Treasurer, and Raphael Ettinger, Honorary Secretary.

Gov. Odell and the State Hospitals Bill.—According to the Evening Post, at the conclusion of last week's hearing at Albany on the State Hospitals Bill, Gov. Odell announced that he would sign it. "I have no desire," said he, "to break down any system. I believe this bill is right, and I am going to approve of it because I believe it is right. There is nothing for those interested in charitable work to fear from this bill, as it is for the betterment of the system of administering the hospitals." The Governor showed considerable feeling towards his critics, and had a sharp colloquy with George F. Canfield, President of the State Charities Aid Association, the principal speaker against the bill. He accused the organization with which Mr. Canfield is affiliated of having been responsible for stirring up the opposition to the measure, and said that there had been great extravagance and mismanagement under the present system. He proposed, under the bill, to get rid of certain persons who had been responsible for some of this extravagance, but had thus far been able to retain office.

Reconciliation in New York Medical Affairs.—The following is a copy of the resolution appointing the committee on conference: *Whereas*, The Medical Society of the State of New York, having appointed a committee to confer with a similar committee from the New York State Medical Association, with the view to a union of the two organizations, and notice of such creation of a committee having been officially given to our President, together with the request that a corresponding committee be appointed by us; *Therefore*, Be it resolved that this Council (the executive board of the Association) appoint for the purpose of the conference in question a committee of five, consisting of Dr. E. Eliot Harris as chairman, and Drs. William H. Biggam, Emil Mayer, Parker Syms, and Frederick Holme Wiggin, to which committee the President is added as a member *ex-officio*.

Alumni of Mt. Sinai Hospital.—The regular annual dinner and reunion of the Association of the Alumni of Mt. Sinai Hospital was held at the "Arena," 39 West 31st street, New York City, February 14, 1902, Dr. E. J. Ware presiding. Among those who delivered addresses were Mr. Isaac Wallach, the President of Mt. Sinai Hospital, Drs. Abraham Jacobi, Arpad G. Gerster, Emil Gruening, Alfred Meyer, B. Sachs and Mr. Louis Wiley, of the New York Times. The following officers were unanimously elected for the ensuing year: Samuel M. Brickner, M.D., President; Albert A. Berg, M.D., Vice-President; Charles Goodman, M.D., Secretary; Martin W. Ware, M.D., Treasurer.

Honor to Dr. Metcalfe.—The New York Sun had the following tribute to pay to Dr. Metcalfe in a recent issue: "John T. Metcalfe, who died at Thomasville in Georgia a week ago Thursday, was scarcely known by this generation, yet in his own he had been one of the most eminent of physicians. Born in 1818 in Natchez, he was graduated at West Point in 1838 and served in the army for two years, mostly in Florida, and then resigned to study medicine. His degree was gained at the University of Pennsylvania in 1843, and then two years in Edinburgh and Paris completed the preparation for his life's work. Not many men can step to the front at the outset of their career and for forty years hold their place against all comers; but Dr. Metcalfe did, and that, too, in spite of a frame at no time robust. As a general practitioner of medicine he wielded an influence in this community more widely felt by his contemporaries, lay and professional alike, than that exercised by any of his associates. As a clinical teacher he might be said to have had no rival, so that in the many years he gave to that absorbing work he left the imprint of his learning and of the surety of his insight on many of the later leaders in his calling throughout the country.

"Dr. Metcalfe's most noticeable characteristics of mind were probably his extraordinary quickness of perception, his readiness in analysis, his strong memory and his sound judgment. They made him the best clinical investigator of disease of his day, as well as the happiest in finding the remedy. He was the very personification of the complete physician. And with friends he was much more. Sydney Smith said no better things than many original with Dr. Metcalfe. His wit—it was always spontaneous—was a delight of which all were glad to partake. If any one could bring a dying man to smile, and that without irreverence or loss of dignity, Dr. Metcalfe was that one. His example remains to his profession, and to his friends the best thing the dead can leave the living—the memory of a most gentle, charming and well-filled life."

American Laryngological Society.—A meeting of the Eastern Section of the American Laryngological, Rhinological and Otological Society will be held at the New York Academy of Medicine, Saturday, March 1st. The following program has been arranged: Address of the Chairman, by H. Holbrook Curtis, New York; An Unusual Case of Nasopharyngeal Adenoids, by Carl E. Munger, Waterbury, Conn.; Unique Case of Postnasal Polypi in a Child, with Specimen, by Geo. L.

Richards, Fall River, Mass.; Report of Four Cases of Polypi Attached to Upper Wall of Maxillary Antrum, Protruding into Nose and Rhinopharynx, by Robert C. Myles, New York; Report of a Case of Temporosphenoidal Abscess, with Presentation of Patient, by James F. McKernon, New York; Peritonsillar Abscess, by Frederick C. Cobb, Boston; Two Cases of Hemorrhage, by W. H. Haskin, New York; Septum Operations under Cocaine and Nitrous Oxide Gas, by B. S. Booth, Troy, N. Y.; Acute Suppurative Otitis Media: Its Etiology, Symptoms and Treatment. Discussion by Wendell C. Phillips, Edward B. Dench, James F. McKernon, New York; The Removal of the Stapes for the Relief of Auditory Vertigo, by Eugene A. Crockett, Boston; Chorea of the Larynx—Report of a Case, by James F. McCaw, Watertown, N. Y.; The Treatment of Tonsillar Mycosis, by Chas. W. Richardson, Washington, D. C.; Epithelioma of the Auricle and Auditory Canal: Operation; Exhibition of Patient, by Thos. R. Pooley, New York; Rhinitis Rheumatica, by W. Freudenthal, New York; Chronic Hypertrophic Rhinitis; Its Treatment, by Z. L. Leonard, New York; Persisting Temperature after Mastoid Operations; Analysis of 100 Cases, by Thomas J. Harris, New York; Deviation of the Nasal Septum: Why Our Corrective Operations Often Fail, by Chevalier Jackson, Pittsburg, Pa.; Operative Treatment of Tracheal Stenosis, Following Intubation for Diphtheria; Exhibition of Three Cases, by Arthur B. Duel, New York; Report of a Case of Empyema of Antrum of Highmore, with Interesting Complications, by H. N. Hoople, Brooklyn; Extrinsic Nasal Neoplasms, by John C. Lester, Brooklyn; Empyema of the Frontal Sinus, by Conrad Berens, Philadelphia; General Consideration of Hyperplasia of the Lingual Tonsil, by Seymour Oppenheimer, New York. The profession are cordially invited to be present.

PHILADELPHIA.

The Philadelphia Neurological Society.—A stated meeting of the Philadelphia Neurological Society will be held on Tuesday, February 25, 1902, at 8.15 p.m. Dr. Adolf Meyer, Director of the Pathological Institute for the New York State Hospitals, will, by invitation, deliver an address entitled "Conditions for Psychiatric Research." Members of the profession are cordially invited to attend. After the address a reception will be tendered Dr. Meyer at the University Club.

Dr. Leidy Honored by French Government.—Dr. Joseph Leidy, Jr., has been honored by the French Government with the insignia of Officier D'Instruction Publique. This decoration was awarded for services rendered during the Paris Exposition of 1900, Dr. Leidy representing the United States upon the International Jury of Hygiene and also being a delegate to the Congress of Hygiene and Dermography.

House Quarantine Likely to be Ended.—The committee of five physicians recently appointed by the Director of Public Safety to consider methods of combating smallpox have recommended, provided certain precautions are taken, the abolition of house quarantine. Guards for maintaining quarantine are now costing the city about $20,000 monthly. The report of the committee is as follows: "As soon as the smallpox patient falls ill he should be isolated. While he is in the house strict quarantine should be enforced. Removal to the Municipal Hospital, however, is advised in all cases. After removal to this institution, prompt measures must be taken to disinfect the premises which he has occupied. Every occupant of the house in which the case has occurred should be vaccinated and if necessary, revaccinated, unless satisfactory evidence of recent successful vaccination, can be shown. When vaccination is refused by such occupants, quarantine should be enforced for a period of eighteen days. The premises should be visited daily by a medical inspector, acting under the instruction of the Board of Health." The Homeopathic County Medical Society opposes the abolition of quarantine.

The Relation Between Chickenpox and Smallpox.—At the Pediatric Society, February 11th, Dr. Jay F. Schamberg read a paper on this subject and reported a small epidemic of chickenpox at the Municipal Hospital. Evidence was given to show that the two diseases were entirely distinct and not gradations of the same affection, as stated by some of the older writers. The epidemic occurred in November, 1900, when 33 persons recovering from smallpox had an attack of chickenpox. The latter disease did not appear until the lesions of smallpox had crusted or disappeared, generally from the twentieth to the thirty-fifth day of the disease. There seemed to be no relation between the two diseases except the strong resemblance in some cases.

University Medical Laboratories to be Begun at Once.—The new medical laboratories of the University of Pennsylvania are soon to be started, although only half of the $600,000 to be expended in their construction and equipment has been raised. The building will be 340 by 245 feet in size and two stories in height. Besides two amphitheaters with a seating capacity of 400 each and smaller demonstration rooms and laboratories, the whole front portion of the building will be occupied by small rooms for special medical work and research. The rooms will be so arranged as to secure the greatest amount of northern exposure.

Physician the Victim of an Incompetent Jury.—After deliberating for nineteen hours the jury in the suit of Mrs. Nugent against Dr. H. M. Righter to recover $5,000 for the death of her six-year-old son brought in a verdict of $1,000 in favor of the plaintiff February 16th. The trial occupied nearly a week, the suit being brought by Mrs. Nugent against Dr. Righter on the ground that the boy died of impetigo contagiosa which resulted from a vaccination by the defendant who, it was alleged, used virus not hermetically sealed. It was further claimed that the physician deceived the plaintiff by telling her the boy had diphtheria. In spite of the defense proving that the impetigo did not develop until twenty-eight days after vaccination and being upheld in his diagnosis of diphtheria and its treatment with antitoxin by a consultant, the verdict as named was rendered. The case will be appealed. A physician who testified for the plaintiff that the method of vaccination used was not a proper one has so aroused the indignation of the profession that it is stated that he will be expelled from the County Medical Society.

Jefferson Hospital Plans Completed.—Final steps toward the building of a new hospital for the Jefferson Medical College have been taken and work will be begun in a few weeks. The hospital will front on Tenth Street and when completed the present building will be demolished to make room for a maternity hospital and nurses' home. The new hospital will be seven stories in height. The out-patient department on the Sansom Street side of the first floor will be separated from the general hospital by a solid wall. The general wards will be on the second, third, and fourth floors, and there will be two private operating-rooms on each floor. Sun parlors will communicate with each ward. On the fourth floor will be a gymnasium with appliances for Swedish movements and the treatment of deformities by exercise. On the fifth and sixth floors will be the private rooms, kitchens, etc. A roof garden

for convalescent patients will cover the entire main building. The J. M. Da Costa Clinical Laboratory will be incorporated with the building. The new hospital will have beds for 250 patients—more than double the number now accommodated in the old building.

CHICAGO.

Chicago Academy of Medicine.—At its annual meeting, February 14, 1902, Drs. W. L. Baum, W. A. Evans, J. G. Kiernan, H. N. Moyer, and E. S. Talbot were elected directors. Dr. W. L. Baum was elected president and Dr. J. G. Kiernan secretary, and the latter hereby becomes secretary and treasurer of the Academy.

Growth of Alexian Hospital.—A report showing the scope of work being done by the Alexian Brothers at their hospital has just been issued. The statistics for the year 1901 show a material increase in the number of patients as compared with the record of 1898, the year the hospital opened. During 1901 the number nursed was 2,709, exclusive of those who applied for treatment at the sanitarium. Of the 2,709 inmates during 1901, but 1,421 paid the full price of treatment; 381 paid a small portion of the cost and 907 were charity patients. City ambulances took 504 persons to the hospital during the year, practically all of whom had been injured in accidents. The hospital is still considerably in debt, and the Brothers in charge will work arduously during the year to secure a material reduction of the amount of indebtedness.

Illinois General Hospital for the Insane.—With the arrival and installation of a hundred inmates from the Illinois Central Hospital for the Insane at Jacksonville, the asylum for the incurably insane at Bartonville was formally opened for the reception of patients February 10th. From now on the State Commissioners of Public Charities will cause to be transferred from the State Insane Hospitals at Jacksonville, Elgin, Kankakee, Anna, and Watertown, with the consent and concurrence of the Superintendents and Trustees of these institutions, such number of incurable patients as the new institution can accommodate. The next installment of transfers will be made later, when 200 patients will be sent from Kankakee and Elgin, one hundred from each place. This institution was built for the care of insane persons for whom there is no hope of recovery. These were so numerous at the State hospitals for the insane that it was believed by the officials that their presence was a hindrance to the successful work on the curable patients. For that reason it was decided to separate them. The capacity of the new institution, while fitted with employees' quarters, domestic buildings, heating and electric plants and storage buildings sufficient to accommodate two thousand patients, is at present limited to about seven hundred, since the cottage and dormitory room will accommodate only this number. Until more ground is acquired the present facilities will not allow for the care of more than that number, and the next General Assembly is depended upon to see that provision is made for more cottages. Meantime, the structure commonly known as the employees' building will be utilized exclusively for the care of patients.

Smallpox.—Three-fourths of all the reported cases of smallpox in the United States are in the territory surrounding and tributary to Chicago and in a population of only about one-third the total population of the country. The data for this statement are found in the current number of United States Public Health Reports, in a tabulation of smallpox in the United States as reported to the Surgeon-General, U.S.M.H.S., December 28, 1901, to January 31, 1902. The cases so reported number 11,107, of which 8,147, or 73 per cent., are in Chicago territory. During the corresponding period last year the proportion was almost exactly reversed—30 per cent. in Chicago territory and 70 per cent. in the rest of the territory. Obviously, the Health Department began its campaign against smallpox none too soon, and the wisdom of its course in appealing to the railway companies as the interest most directly concerned, from a financial standpoint, and as the most effective working agency, is already demonstrated. They have taken hold of the work in a thoroughly business-like fashion, and it is not too much to expect that the epidemic will be practically under control within the next three weeks. There will be no occasion for insuring against smallpox, as is being done in England, if the principles of the vaccination creed be faithfully carried into effect. Great immunity of Chicago from the disease still continues. During the last week 28 suspect cases were examined by the medical inspectors, but only 4 were found to be genuine cases.

Amphitheater at Mercy Hospital Dedicated.—The new clinical amphitheater at Mercy Hospital, one of the finest in the West, was dedicated Wednesday evening, February 12th, in conjunction with a regular meeting of the Chicago Medical Society. Representatives of the Northwestern University Medical School took a leading part in the dedicatory exercises. Dr. Robert D. Shepard, who has been closely associated with the work of Mercy Hospital as well as that of Northwestern University, spoke of the history of the two institutions, telling how, though the University and the Hospital are controlled by different managements and have been for a number of years, they have coöperated in medical and surgical work. In the unavoidable absence of his father, Dr. Nathan Smith Davis, Sr., Dr. N. S. Davis, Jr., acted as a substitute for him. He said the Mercy Hospital was founded in 1849, there being no hospital in Chicago prior to that time. In order to found the hospital, Dr. N. S. Davis, Sr., delivered a course of public lectures in Chicago, by means of which a small sum of money was raised; twelve beds were purchased, and a free hospital was opened in an old building across Rush Street bridge on the North Side. The Sisters of Mercy took charge of the institution thus founded late in the following winter. From those few beds and from the small assemblage of medical men and of patients has grown the present institution, situated now on the corner of Twenty-sixth Street and Calumet Avenue.

Medical Education.—The address of the evening was delivered by Dr. John B. Deaver of Philadelphia, who selected for his subject "Medical Education." The course of study in a medical school should be well balanced and proportionate, and this aim should be kept in mind. The time given is too short to fit a man to become a specialist, but is only sufficient for a groundwork that will permit him to follow his bent, either in post-graduate schools, or in that larger and greater school of personal experience—the daily routine of practice. Even a rapid review of the curricula of the various medical schools will show that in most this balance is not maintained. Some devote too much time to laboratory methods, some to surgery and anatomy, and in others the preference is given to internal medicine. This unevenness is usually due to the domination of one branch of the faculty over the others, and suggests the remedy of each department asking for only the necessary time for the ground-work principles of their branch, and not that necessary for the instruction of future specialists. A college course should be practical. For instance, in some medical schools nearly as much time is given to instruction in chemistry as is given to anatomy, and yet the graduate is hardly able to examine a specimen of urine for albumin with certainty and despatch. Clinical and didactic teaching each have their place. Were it possible, the ideal

method would be a presentation clinically, in a logical order, of all the varieties and stages of disease, but this is manifestly impossible, and didactic teaching must always fill up the gaps left by clinical teaching and be useful in reducing the lessons learned clinically to a systematic and rememberable classification. Thus both kinds of teaching have their place; but there is little doubt that a lesson learned at the bedside or operating-table is more real and applicable to the student than a lesson learned from a didactic lecture. A spirit of commercialism is one of the greatest enemies of a medical school. A large production at a cheap rate may be a good enough aim for a business house, but this spirit is fatal to a medical school. Too many schools seem to take pride in their large enrolment of students, forgetting that at the same time the teachers and clinical material are entirely inadequate for the proper instruction of so large a body of men. Nothing is of greater importance to the body politic than the proper instruction of those who are to have the care of the health of the community on their shoulders. There is not, and never has been, a higher calling than that of the teacher, and a teacher of medicine is one of the highest in this calling. The dignity of the calling is seriously debased by its being occupied by men who, in order to obtain even a respectable livelihood, must make their high position subservient to their practice. Dr. Deaver then considered those principles that are the rock upon which the enduring edifice of medical education must be reared. They are three—anatomy, physiology and pathology. With a thorough practical working knowledge of this triumvirate, all knowledge of medicine is possible of attainment. Where is the surgeon who does not, each day of his life, call to his aid his knowledge of anatomy and pathology, or the physician who is not constantly in need of a knowledge of physiology and pathology in making the simplest diagnosis or in performing the simplest operation of surgery?

Tribute to Dr. N. S. Davis.—Among the pioneers of those who have done most for the advancement of medical education stands the name of one of the members of the Chicago profession. He referred to Dr. N. S. Davis, who as long ago as 1839 began a series of articles asking for improvement in medical schools. Almost the first in the field, his conscientious and able efforts were finally crystallized into the American Medical Association. Thus it is seen from its very inception the primary object of this great bond of unity between the most widely separated members of the American profession was the advancement of medical education. That its purpose has been productive of valuable results there can be no question, and Dr. Davis has been able to see results worthy of the greatest congratulation in the advancement of the medical schools of the country.

Peroration.—Kingsley in "Westward Ho" drew attention to the fact that the tide of immigration was ever toward the west, and it would seem that medicine is following in the track of the westward tendency in the United States. It was not many years ago when the East held the palm of medical education; but today we of the East must bow to the progress of our Western brothers, whose achievements speak so loudly and who, with no uncertain voice or faltering hand, have taken a place in the front ranks of medical attainment, and have raised the banner of Esculapius to the virgin winds of the great West.

A Case of Carcinoma of the Head of the Pancreas.—At a meeting of the Chicago Pathological Society, held February 10th, Dr. Frank Billings presented this case. The patient was a man, fifty-three years of age, a German, a leather worker by trade, who was admitted to the Presbyterian Hospital on October 21, 1901. His family history was negative and he had not been sick until the present illness began five months before his admission. He then noticed slight dizziness and weakness on rising in the morning and in a few days his physician told him that his eyes were yellow. A general jaundice followed, gradually increasing until his whole body was intensely discolored. The jaundice was associated with a sleepy feeling and with much itching of the skin. He lost gradually in weight and in five months before his admission weighed 33 pounds less than at the beginning of his illness. His bowels were usually loose with large stools. He had no pain, chills, fever or sweats at any time. There was no nausea or vomiting. Examination on admission showed an emaciated jaundiced patient with sclerosed arteries. Negative findings in lungs and heart; liver dulness beginning at the fifth interspace in the mammary line and extending three finger-breadths below the costal border. The left lobe of the liver appeared larger than the right and was nodular and somewhat tender to the touch. The abdominal muscles were so rigid that it was impossible to tell the condition of the gall-bladder. The spleen was not palpable. The urine contained a great deal of bile pigment but no other abnormal ingredient at any time. At no time was sugar found. While in the hospital the patient usually had a slow full pulse, subnormal or normal temperature and normal respirations. His appetite was poor, he was sleepy and drowsy much of the time and indifferent as to the final outcome of his disease. Blood examination showed 2,640,000 reds; 8,700 whites; and 58 per cent. of hemoglobin. The blood-corpuscles and plasmodia were yellow-stained. The time of coagulation of the blood was twelve minutes (Wright's method). The bowels moved two or three times each day and the total fecal excretion was large for each twenty-four hours. During the stay in the hospital the patient had no nausea, vomiting, pains, chills, fever or sweat. He died December 20, 1901. The autopsy made by Professor Hektoen, December 21st, revealed carcinoma of the head of the pancreas, biliary obstruction, dilatation of the gall-bladder and hepatic ducts, with general jaundice, biliary cirrhosis, cystic dilatation of pancreatic ducts, secondary carcinoma of the liver and of the peripancreatic and inguinal glands, chronic gastro-enteritis, chronic ulcerative colitis, chronic nephritis, chronic pulmonary tuberculosis, adhesive pleuritis, sclerosis of the aorta, epithelioma of esophagus, and Meckel's diverticulum.

CANADA.

Obituary.—Dr. J. A. Fife of Peterboro, Ont., died on the morning of February 12th. Deceased had been a practitioner of that town for many years and was a native of the county, having been born there in 1838. He was graduated from the Toronto School of Medicine and from Victoria University, Toronto, after which he took a post-graduate course at Bellevue, New York. During the American Civil War he served for two years in the Northern navy.

Value of Vaccination Proven.—Since May, 1901, there have been in the Montreal Civic Hospital two hundred and forty cases of smallpox, not one of these patients having been vaccinated before being brought to the hospital. The efficacy of vaccination as a preventive of smallpox is effectively illustrated by the fact that for months a staff of doctors and nurses, eighteen in number, have been in almost hourly attendance upon these patients, but not one of them has contracted the disease.

Medical Inspection of Schools in Montreal.—At the last regular meeting of the Medico-Chirurgical Society of Montreal the question of the medical inspection of schools was under discussion. Papers were con-

tributed on the subject by Dr. Ruttan, Dr. Tait McKenzie, Director of Physical Training, McGill University, and Dr. Charles H. Church. Dr. Ruttan's paper dealt generally with the whole matter; Dr. McKenzie's paper referred particularly to the deformities among school children resulting from defective seats and desks, while Dr. Church's paper dealt with observations taken from the schools of Montreal, particularly referring to sanitary conditions. There was a general discussion following the reading of these papers, and it was decided to take up at a future date the whole question of the medical inspection of schools in that city.

Increase of Insanity in Ontario.—According to the report of the inspector of lunatic asylums for the Province of Ontario, there were in these institutions on September 30, 1901, 4,604 patients as compared with 3,318 twelve years ago. The population for the different asylums in the Province is set down as follows: Toronto, 724; London, 1,034; Kingston, 509; Hamilton, 1,029; Mimico, 605; Brockville, 613. A comparison of the relative increase of insanity with the population shows that while the provincial population has increased from 1,396,091 in 1861 to 2,182,942 in 1901, or 56 per cent., the number of insane and idiots, officially known, has increased in those forty years from 1,631 to 5,880, or 260 per cent. The ratio forty years ago was one to 856; it is now one to 371. Of course, there is a great change in public sentiment within that time with regard to placing patients in asylums for treatment.

Prohibition in Ontario.—On October 14, 1902, the people of Ontario will have the chance of saying whether prohibition of the liquor traffic is to obtain in that Province. "The Liquor Act, 1902" is now before the Legislature; and it provides for a referendum on the above date. The question is of interest to the profession of medicine as certain clauses in the bill show. If carried at the polls, prohibition is to come into force on May 1, 1904. After that time the dispensation of all fermented, spirituous and malt liquors, and all drinkable liquors which are intoxicating, will be in the hands of the wholesale and retail licensed drug-houses and shops, and with the doctors. Retail druggists will only be permitted to sell "liquor" to private individuals under *bona-fide* doctors' prescriptions; and the quantity allowed to be kept by any retail druggist or physician will be not more than five gallons. A sick person will be allowed to keep liquor in his room if prescribed for him, but he must not let any other person drink it there. Hospitals will be permitted to keep it, but only for the use of patients and that on a physician's prescription.

New Medical Building for Toronto.—A deputation from the Medical Faculty of Toronto University waited on the Ontario Government during the past week with the object of securing Government aid to the extent of $50,000 for the purpose of erecting a new building for the Medical Department. The estimated cost of this new building, which is to be known as the physiological building, is $125,000; and it is proposed that part of it will be used by the Arts Department of the University. On this account the Medical Faculty thinks that the Government should place the above sum in the estimates, when they will undertake to finance the balance, $75,000. Dr. Reeve, Dean of the Medical Faculty, headed the deputation, and presented a by-law passed by the Trustees of the University authorizing the construction of the new building, which he asked the Government to sanction. The Government was not very definite in its promises in the matter, the Minister of Education, the Hon. Mr. Harcourt, throwing out the suggestion that the Medical Faculty undertake to raise the entire sum, and then charge the Arts Faculty $2,000 per annum, the interest on $50,000.

Toronto Clinical Society.—At the regular monthly meeting of the Toronto Clinical Society, held on the evening of February 5th, Dr. E. E. King showed two patients who had had fracture of the spine. Three interesting cases of capsular nephrotomy were also reported, the first by Drs. W. P. Caven and George A. Peters, the other two by Dr. Alexander Primrose. Dr. Caven's case was a man, aged thirty-four years, who in the summer of 1899 was first told that he had Bright's disease. His kidneys were said to be sound in 1892, as he was passed at that time for life insurance. When he came under the observation of Dr. Caven he was passing from 60 to 80 ounces of urine in the twenty-four hours, with three to seven grams to the liter of albumin. Hyaline, granular and fatty casts were also present in great abundance; urea, from 1½ to 2 per cent. On January 3d of the present year he was placed under chloroform and Dr. Peters performed encapsulation of both kidneys at one sitting. Before the operation there had been a gradually-increasing number of casts in the urine, but there was none found in the following twenty-four hours. There was no material change in the albumin or in the quantity of urine passed or in the amount of urea. The patient was very ill for some days after the operation, but his general health soon began to improve. Dr. Caven then referred to the paper of Dr. Edebohls on the subject. Dr. Primrose stated that the first case he described was performed before Dr. Edebohls' paper had been published. His first operation was performed on the right kidney and the second on the left. The first was reported at considerable length, being illustrated by a carefully-prepared chart and by two photographs of the boy, who was ten years of age, one taken before and the other after the operation. For six months the boy had general anasarca and ascites. Paracentesis abdominis had been performed seventeen times. Albumin was present in the urine—1.6 per cent. The urine increased from twenty to forty ounces after the operation, and the albumin diminished to .03 per cent. Later Dr. Primrose cut down upon the left kidney and removed entirely the kidney capsule. At the first incision he followed Harrison's suggestion, but at the second he followed that of Edebohls and brought the kidney out of the wound. The child was critically ill for some days subsequently, but gradually recovered and the renal symptoms underwent remarkable recrudescence. The general edema disappeared. A very animated and extended discussion followed the reporting of these cases in which it appeared that the consensus of opinion was that Dr. Edebohls had not given to Mr. Harrison due credit for having performed the first operation, even though it had been performed on a case of acute disease.

GENERAL.

Atlantic County Medical Society.—At a meeting of the Atlantic County Medical Society, held February 5th, the following officers were elected: President, William Edgar Darnall; Vice-President, T. Senseman; Secretary and Treasurer, Edward Guion; Reporter, A. B. Shimer.

Cincinnati Obstetrical Society.—At a recent meeting of the Cincinnati Obstetrical Society the following officers were elected: President, Julia W. Carpenter; Vice-President, Wm. Gillespie; Secretary, Magnus Tate; Recording Secretary, E. S. McKee; Treasurer, C. D. Palmer.

American Laryngological, Rhinological and Otological Society.—The eighth annual meeting of the American Laryngological, Rhinological and Otological

Society will be held in Washington, D. C., June 2, 3, 4, 1902.

Scarlet-Fever Serum.—Prof. Leyden announces that he has perfected a new serum for the prevention and cure of scarlet fever. It is said to be derived from the blood of patients infected with the disease. A number of tests made in a Berlin hospital have been successful.

Virchow Hospital.—It is proposed by the municipal authorities of Berlin to erect a hospital to be dedicated to Virchow. It will accommodate 1,700 patients.

Hospital Gift for Greenwich.—Robert M. Bruce is to provide Greenwich, Conn., with an isolation hospital for the safe treatment of contagious diseases.

Gift to Johns Hopkins.—It was learned last week that 176 acres of land in the northern suburbs of Baltimore have been unconditionally donated as a new site for the Johns Hopkins University. Arrangements have been practically completed for the transfer of the land on February 22d, the date of the jubilee celebration of the University.

Battle Creek Sanitarium Fire.—The Kellogg Sanitarium was entirely destroyed by fire early February 18th. Four hundred patients, who were in the hospital and the main building, were taken out before the flames reached them. But two accidents occurred during the removal of the patients. One woman and a girl, names unknown, became frightened and jumped from the third-story windows. Both broke their legs. The origin of the fire is unknown. The main building was 312x100 feet and six stories high. The loss will amount to at least $300,000. As soon as the fire was discovered watchmen ran through the corridors arousing the sleeping patients on each of the six floors. Many of them were unable to help themselves, and were carried to places of safety by the nurses. The corridors filled with smoke very rapidly, and about half of the inmates of the building were forced to come down the fire escapes. The sanitarium stood on a hill, and the water pressure was low, therefore the water supply was insufficient. The managers of the sanitarium are positive that no lives were lost, as each room was visited three times by a nurse before the building was abandoned. The buildings will be rebuilt immediately.

Obituary.—Dr. John L. Million, of Springfield, Ohio, died last week from pneumonia. He was seventy-five years old. He was a surgeon of General John A. Logan's regiment during the Civil War, for thirty years was chief medical examiner of the Ancient Order of United Workmen and long a pension examiner.

Dr. W. A. Dudley, one of the oldest physicians in Petersburg, Va., died last week of pneumonia, aged seventy years. He had practised medicine there for fifty years. During the gold fever in California he and his mother drove from Virginia to that State.

Dr. Thomas Neall Penrose, medical director, U. S. N., retired, died Thursday, Feb. 13th, at the Naval Hospital in Philadelphia from heart and kidney trouble. He was retired in 1897.

CORRESPONDENCE.

CURES EXTRAORDINARY.

To the Editor of the Medical News:

Dear Sir: Doubtless you are ever ready to chronicle new and wonderful strides in the healing art. With that belief, I respectfully submit the following:

My attention was recently attracted by the advertisement of Prof. Thos. F. Adkins, of Rochester, N. Y., who claims to cure the lame, the halt and the blind by means of his newly invented science, which consists of three parts mental powers and one part drugs (payable in advance). No disease or injury is of too complicated a character or of too long standing to baffle his seemingly supernatural skill.

Having worn a full-length artificial limb for several years, I was naturally led to hope by the professor's past achievements that it would be a very simple matter for him, by means of his highly developed mental endowments, to start in motion the healing vibrations which would change my patented limb into one of flesh and blood.

Accordingly, I wrote him in substance the chronic nature of my complaint; that my limb was devoid of feeling except for an apparent tingling in the toes occasionally; that I had practically no control over the knee-joint, and that, while approximately of the same length as the other, it did not appear so well developed, etc. By some inadvertence, I failed to state in so many words that it *was* a wooden leg, but doubtless such a slight omission from the symptoms would have no influence on the very clever diagnosis with which I was favored and which is enclosed herewith.

Truly, what a blessed era has been attained when one's physical or mental troubles will disappear by simply hiring another to think of them!

Should my case progress favorably, I shall take pleasure in reporting the same.

C. A. Sargent.

240 W. 34th Street, New York.

January 24, 1902.

"NEW YORK INSTITUTE OF PHYSICIANS AND SURGEONS AND THE THOMAS F. ADKIN SANATORIUM.

Rochester, N. Y., January 11, 1902.

"C. Sargent,
"N. Y. City.

"Dear Friend:

"Your request for free diagnosis came duly to hand. I have given your case my careful consideration, also consulted with my specialists relative to it and it is our combined opinion that you are suffering from uric acid diathesis with rheumatic manifestations, traumatic injury to limb causing partial paralysis.

"These troubles, while not yielding to the ordinary forms of treatment, magnetic, mental or medicinal, respond promptly to Vitaopathy. I have treated many cases *exactly like yours.*

"This method is original with me, being the result of years of study and experience. It is certain in its effects and never fails to bring about immediate and satisfactory results. My staff of specialists have spent years in treating such cases as yours in the ordinary practice of medicine. They are now devoting their entire time to the application of Vitaopathy to such cases, and the results are truly marvelous.

"If you allow me to take up the treatment of your case, I will do so with every confidence of perfecting a *permanent cure. I have hundreds of similar cases* under treatment, all testifying to the marvelous benefits received. As a reasonable person, you know that with the experience gained in treating so many similar cases, it is natural for me to understand such better than the ordinary physician who, perhaps, has only a few cases each year. 'Practice makes perfect' and it applies to the treatment of diseases as well as any other line. The more we practise the more we learn and the larger percentage of cures we make. I have the advantage of treating tens of thousands annually, while the ordinary physician treats but a few hundred. Remember that my treatment is especially prepared for each individual case. If you went to specialists, such as I have in my employ, they would charge you from $10 to $20

for an examination alone. I give you the attention of these specialists free. They have made a life study of certain diseases which their specialty covers, and if you place your case in my hands, it will have the very best attention that recognized specialists can give it. They will study your case continually and offer suggestions which will aid the treatment in curing you in the shortest possible space of time.

"The fact that my treatment is the only guaranteed treatment before the public ought to convince you of its merits. If you order a month's treatment and are not cured or materially benefited within two weeks' time, according to the terms mentioned in the enclosed guaranty contract, I will immediately refund your money. Now, this is certainly fair.

"For financial responsibility, honesty and integrity, I refer you to the Flour City National Bank of this city. For an immediate reference relative to the treatment, I invite you to write to Professor Geo. W. Savage, Warren, Pa., also to John C. Nelson, Dayton, Tenn. Both of these gentlemen have recently been cured by the Vitaopathic treatment. I shall be pleased to furnish other references if you so desire.

"At the low rate I charge, you cannot afford to be without this treatment—without all the expert attention I give you. If the druggists in your city were able to fill the prescriptions which I will have filled for you at my laboratory, their price for the remedies alone would be more than I ask for the entire treatment. The cost of a month's treatment is $5.00. Is there a physician in your city who could afford to treat you at this rate, giving you treatments twice a day as I do? Certainly there is not, and I am enabled to do this only because I treat so many cases that I can keep my specialists profitably employed all the time.

"A report of your case has been placed on file, so that upon receipt of your order there will be no delay in beginning treatment.

"You cannot afford to miss this opportunity. Remember that I have cured hundreds of cases that have been regarded as hopeless—cured them after all other methods had failed. Whether you take my treatment or not, I should like to hear from you. I will be glad to correspond with you relative to your case. I have the interest of humanity at heart aside from any financial consideration.

"If you will order a month's treatment within fifteen days from the date of this letter, I will give you my new course of instruction in Magnetic Healing absolutely free. The regular price of this course is $3.00. In order to introduce it in your community I have decided to give it to you free of charge. All I ask in return is that you recommend it to your friends whom you think might be interested. It is the best course in magnetic healing on the market. I guarantee this. I am sure you will be greatly pleased with it. I should like to hear from you by return mail so that I may know you have received this communication.

"Most cordially yours,

"INSTITUTE OF PHYSICIANS AND SURGEONS,

"THOS. F. ADKIN,

"President.

"P.S. I am sending you, under separate cover, my free book and circulars which I should like to have you read with great care, also fill out the symptom blank that you will receive with my circulars and return it to me with your order so that I may give your case a more thorough diagnosis.

"In replying, kindly use the enclosed envelope and your communication will receive prompt personal attention."

TRANSACTIONS OF FOREIGN SOCIETIES.

French.

LUMBAR PUNCTURE AND FRACTURE OF THE SKULL—DIAGNOSTIC DIFFICULTIES IN INJURY TO THE SPINAL CORD—DUODENOSTOMY—INFECTIOUS ENDOCARDITIS—SUICIDAL MANIA DURING TYPHOID FEVER—MALTOSE IN THE LIVER AFTER DEATH—AMYLOLYTIC FERMENT IN THE BLOOD OF HEALTHY CHILDREN—ANTITUBERCULOUS SERUM—TRANSMISSION OF HUMAN TUBERCULOSIS TO ANIMALS—INOCULATION OF WHITE RATS WITH HUMAN CANCER—ACUTE TETANUS CURED BY CARBOLIC ACID—EXPERIMENTAL MENINGITIS.

DURING December the French Societies were active. Numerous interesting subjects were discussed, the following being the most important:

REYNIER at the Surgical Society, December 11, 1901, stated that he has recently had a case in which lumbar puncture was used for the diagnosis of fracture of the skull. The man was brought to the hospital in a deep degree of coma, with a paralysis of the left side. It was difficult to determine between a diagnosis of fracture of the skull and a simple hemorrhage into the brain, which would have made it a medical case. On the day after admission a lumbar puncture was made that resulted in the withdrawal of bloody fluid. This established the former diagnosis. At the operation of opening the skull a fracture of the parietal bone was found, with depression of the fragments, tearing of the dura mater and lacerations of the frontal and parietal convolutions of the brain. Thirty-six hours after the operation the patient died. The utility of lumbar puncture in these cases is still an open question, because there are instances in which withdrawal of the fluid by it has been of good effect and other instances in which no result whatever has followed.

TERRIER stated that the paper which Walther presented at the preceding meeting on a case of complete division of the spinal cord had induced him to explain to the Society the difficulties concerning the proper appreciation of symptoms proceeding from injuries to the spinal cord. His illustrations were drawn from facts collected by him during experiments on the horse. Frequently before the dura mater had been cut there appeared a light form of paraplegia. Later in another series of experiments on the dog of a similar character under the direction of Professor Longet, during which every effort was taken to avoid injuring the spinal cord itself, in removing the spinous processes it was found that paraplegia appeared without even so much as touching the spinal cord itself.

HARTMANN detailed the history of a woman who, after drinking a quantity of caustic liquid, showed signs of stricture of the esophagus which prevented all feeding by the mouth. At the operation he found the stomach so much retracted by scar tissue that it was impossible to perform a gastro-enterostomy or a gastrostomy. In order to assure the proper nourishment of the patient he was compelled to open the duodenum. This duodenostomy had immediate satisfactory results, but unfortunately the patient thought that she had the power to feed herself again by the mouth and made the attempt. The result was that she died in a few days, with purulent vomiting of gastric origin.

CLAUDE, at the Medical Society of the Hospitals, December 13, 1901, described two cases of infectious endocarditis, both latent, one with a subacute progress and the other with a chronic progress. The first case involved a man thirty-six years old for eight days afflicted with intense dyspnea with cyanosis of the extremities, albuminuria and high fever at the time of his admission. Over the chest were heard the signs of universal bronchitis with numerous loud râles.

There were, however, no murmurs at any of the valves of the heart, as apparently the sounds were hidden entirely by the signs of the bronchitis. Twenty-four hours later the man died in coma. At the autopsy there were found abundant wide-spread vegetations. Over the sigmoid valves of the aorta was a fibrinous exudate covered with small ulcers. In these deposits a large number of cocci were found on bacteriological examination. These were also abundant throughout the blood and at the sites of small hemorrhagic spots surrounded by infiltrations of embryonal cells, frequent in the liver and spleen. The man had, therefore, suffered from a septic endocarditis with ulcers and vegetations in the aorta. These have been a point of departure for a large number of microscopical emboli in the principal viscera. The second case was that of a woman thirty-four years old, received at the hospital in a state of prostration and advanced cachexia. Eight months previous she had had an attack of rheumatism in many of the joints of the body, in consequence of which she had become slowly and progressively invalidated. During her stay in the hospital this woman had not been able to take much nourishment, complained of pains in the abdomen and had constant diarrhea, with from time to time bleeding from the bowels and vomiting of bile. She gradually wasted away and died without having had fever while in the hospital. Her heart showed the presence of a diastolic murmur at the base, which was ascribed to an old insufficiency of the aorta. At the autopsy there were found tuberculous ulcerations over most of the surface of the intestines and throughout the lungs. The heart showed over the valves of the aorta scattered vegetations covered with fibrin. In one of the vegetations there was a small abscess containing a large number of streptococci, which did not, however, possess much virulence. The liver, spleen and both kidneys showed on microscopical examination the lesions of toxic degeneration most marked in the liver and kidneys. The diagnosis here appears to have been a chronic septic endocarditis which ended life by causing a toxemia.

Souques read a communication in the name of Ribierre and himself concerning a young woman who had attempted suicide on the sixteenth day of typhoid fever by jumping out of a second-story window. The woman had been afflicted for forty-eight hours previously with a dread lest she be cut into small pieces and disemboweled while alive, because for several days previously she had not been able to control her urine. The authors stated this fact as a peculiar one for the delirium of typhoid fever and to indicate its possibilities. Even in this disease, it appears that fixed ideas with hallucinations are possible which give rise to impulse to sucide. It is therefore wise to watch with greater care all typhoid-fever patients who become delirious.

R. Lapine and Boulud (Lyons) at the Society of Biology, December 14, 1901, desired to state that in addition to glucose a small quantity of maltose can be found in the liver after death. They have been able to show the existence of this form of sugar in the livers of dogs very frequently, although they were nourished entirely with meat. The livers were left several hours at the temperature of their laboratory and then they were treated as follows: By means of ether maltosazone was isolated from glucosazone. Then, after hydrolyzation of the extract of the liver, examination with the polariscope showed that the deviation to the right had been decreased while the power of reduction had been increased. They have also been able to observe the presence of maltose in the blood of dogs the livers of which contained it after death.

Nobecourt and Sevin said that in children less than two years old the amylolytic power of the blood serum is so great that one c.c. of serum always produces when mixed with starch in twenty-four hours at a temperature of 37° a quantity of glucose which varies between 0.005 and 0.0199 gram. Before the end of the second month of the child's life this amylolytic power of the blood is very feeble or absent. At whatever age it may be strong, it never seems to exceed the strength of producing more than 0.0299 gram. In children of greater age and in youths the lowest degree of amylolytic power is after all high, and the quantity of glucose produced is comprised between 0.02 and 0.0299 gram.

Arloing (Lyons) has been experimenting with a peculiar action of antituberculous serum which favors infection by the bacillus of tuberculosis attenuated under new conditions. If, into the veins of the rabbit, a mixture is injected made up of a variable amount of antituberculous serum and hemogeneous fluid-cultures of the bacillus of tuberculosis, there always takes place an exaggeration of the lesions of the disease in the organs of the abdomen and chest and their coverings. From these researches it seems likely that although administered by the veins and at the same time with an attenuated culture, the antituberculous serum has no power to arrest the disease; on the contrary it seems almost to favor it. Moreover, if serum is injected repeatedly in the tissue around the point of inoculation and sometimes in advance of the latter, it does not always afford any resistance by the animal to an intravenous injection of the culture of the tubercle bacillus.

S. Arloing (Lyons), at the Academy of Medicine, December 24, 1901, related the results of three series of experiments concerning the inoculation of animals with human tuberculosis. The bacilli were taken from various sources, such as the sputum, fluid from pleurisies and the like. The inoculation was intravenous and carried out upon kine, sheep and goats. The lesions found in all of these animals were chiefly in the form of granulations, confluent or discrete, in the lungs, liver, spleen, nervous ganglia and kidneys. As a rule they were distinguished by a low-grade cascation. Similar to these experimental results were those already obtained previously, made by the same author and tending to show that human tuberculosis can be transmitted to animals. In this first series there were twenty-three animals inoculated. If such authors as Koch and Schütz have failed in their inoculations, Arloing claims that it was because they used cultures of feeble bacilli on the one hand, and that the doses of whatever cultures were used were really too small. Arguing from his own results this author believes that he is entitled to draw the following conclusions: (1) The virulence of the tubercle bacillus is a variable quantity and capable of adapting itself to certain organisms. It seems, therefore, certain that the human bacillus can certainly attack and grow within certain animals with an activity no less marked than that of the bovine bacillus. (2) One may produce in cultures pure human bacilli which are capable of infecting the kine, the sheep and the goat. (3) Since it is possible to find such a result, it is not necessary to claim a distinct kind of tuberculosis for either. (4) The unity between the tuberculosis of man and of animals due to the bacilli of Koch is indisputable. (5) Koch and Schütz are not justified after their experiments in claiming an absolute distinction between human tuberculosis and animal tuberculosis. (6) It is therefore necessary to continue to carry out all the precautions concerning infected meat that have hitherto been the rule.

Mayet, at the Academy of Sciences, December 9, 1901, read a contribution in which he set forth results

of experiments for the proof of the transmissibility of human cancer to white rats. These confirm the previous researches made by him and read before the Academy almost eight years ago (1893). In three cases Mayet has seen appear after repeated injections of an aqueous maceration of cancer without filtration small nodules in the kidneys of epitheliomatous type. In three other animals in the same organs he found cavities which were evidently the production of new growth. The introduction of cancerous tissue into the peritoneal cavity had in two animals the effect of producing small nodes in the liver and kidneys; in two other rats the liver was more actively attacked, showing multiple small areas of neoplasm and even presenting a large mass of neoplasm 2 c.m. by 2.8 c.m. in diameter. Three rats which had received a filtered maceration of sarcoma showed a neoplasm of the liver identical to the preceding on gross examination. Unfortunately no microscopical examination was made. In a third case the introduction of cancerous matter into the peritoneal cavity produced on the digestive tract, especially the stomach and small intestines, about twenty small tumors the size of a pea. His total experiments were the following: Positive results in five cases, doubtful results in seven cases, and negative results in forty-two cases.

ENRIQUEZ, at the Medical Societies of the Hospitals, December 20, 1901, reported a case of tetanus cured by injections of carbolic acid carried out by Bauer and himself. The woman had received an injury of the index finger followed by universal tetanus of rapid onset and progress, with symptoms referable to the medulla oblongata, namely, disassociation of temperature and pulse, attacks of dyspnea, vomiting, etc. During the first four days of the disease she was treated without results with chloral hydrate and injections of antitetanic serum; on the next two days injections of a solution of carbolic acid were used, 4 c.c. the fifth day and 6 c.c. the sixth day. Then without any remission having become apparent, the treatment was changed to the following: Each day 150 to 200 grams of blood were withdrawn, followed by the infection of 200 grams of artificial serum to which were added 3 c.c. of a 2-per-cent. solution of carbolic acid. At the end of two days of such treatment the convulsions had almost disappeared. The blood-letting was discontinued and only the injections of carbolic acid and blood-serum continued. To-day the cure is complete. This observation appears to prove that notwithstanding the unfavorable results obtained in experiments by Courmant, Doyon and Josias, it is rational to employ injections of carbolic acid in all cases of serious tetanus which threaten to end fatally in a short time.

DELILLE, at the Society of Biology, December 21, 1901, reported that he has produced plastic spinal meningitis experimentally by sclerosing poison by the bacillus of tuberculosis. The inoculation was made upon dogs through a lumbar puncture with a definite quantity of this poison (*i.e.*, the chloroform-bacilline of Auclair). After about three weeks' delay a chronic meningitis was present which ended in paraplegia with contracture and amyotrophy. These results were like those obtained previously with the caseating poison of this germ (ethero-bacilline). The examination with the microscope gave strongly typical lesions. The tubercles were formed of polynuclear cells at their centers and mononuclear cells of epithelial type in the middle zone and of lymphocytes in their autozone. There was also a large amount of fibrous tissue. From these experiments it is possible to conclude that the sclerosing and caseating poisons of the bacillus of tuberculosis produce in the meninges results of equal intensity.

SOCIETY PROCEEDINGS.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Stated Meeting, Held December 4, 1901.

The President, Alexander Lambert, M.D., in the Chair.

Treatment of Lobar Pneumonia.—Dr. Charles E. Nammack read a paper with this title.

Discussion.—Dr. W. Gilman Thompson said that the paper was full of good sense. He sometimes thought it was a misfortune not to have some definite plan for the treatment of such a disease as pneumonia, yet cases of pneumonia vary so much that a method of treatment applicable to all varieties could not be formulated. He had used the inhalation of creosote and other substances and had watched this method of treatment as employed by others in hospital service, but he had not been convinced that it had any modifying influence on the disease. The treatment was based upon the idea that the inhaled substance reaches the focus of the disease, but the affected lung is occluded and therefore the substance cannot be drawn down into that part of the lung where it is most needed. It had been shown experimentally that when such vapor is inhaled it does not penetrate very deeply. He had practically abandoned this treatment because of the annoyance it caused the patient. With regard to the use of poultices and cold applications, he had never seen any difference in the effects of these various topical applications, and hence he was governed by what seemed to give the most relief. When there was much pain a large poultice would give relief, but ordinarily he did not favor the use of poultices, as they disturb the patient. Some time ago the speaker had made experiments to determine how deeply external heat or cold penetrates the body. He had had a patient suffering from an empyema who had a fistula eleven inches deep. A thermometer was inserted into this fistula and hot and cold applications were made externally, but he had never been able to affect the temperature of the parts beneath more than one-eighth of a degree. If such applications were used with this object in view they were certainly fallacious. The treatment was narrowed down to aiding elimination of toxic material and regulating the tension and strength of the pulse. When the pulse was full and bounding, he made use of nitroglycerin or, quite early and for a short time, he used aconite. When the opposite conditions were present, it was very desirable to reënforce the peripheral circulation by such remedies as Dr. Nammack had mentioned. He had not personally made use of the suprarenal extract in these cases, though this agent certainly raises the tension and gives the heart peripheral resistance. Physiological experiment, as well as clinical experience, demonstrates that this will often improve the character of the cardiac contractions. For this reason suprarenal extract might be useful in some cases showing much cyanosis. In some few cases in which he desired to influence the heart, he made use of digitalis. The latter, however, had the advantage that it could be given hypodermically. With regard to the treatment of the temperature, he was in accord with the author of the paper; he seldom attempted to reduce the temperature by cold applications unless the temperature rose above 104° F., or the patient suffered much discomfort from the fever. In such cases he used cold sponging or the cold pack. The latter was very soothing and was a general stimulant to the nervous system. He did not believe in the use of the Brand bath for penumonia, and when penumonia complicates typhoid fever he discontinued the baths, as

he had seen disastrous results from continuing them. It was important to keep the bowels active, securing at least one good evacuation daily. It prevents intestinal fermentation; anything which tends to distend the abdomen acts unfavorably by its mechanical effect on the diaphragm and by reason also of the coincident auto-intoxication. He always disliked to see a pneumonia patient with an attack of flatulent dyspepsia, and when it occurred, he used salol, turpentine stupes and the rectal tube. The use of alcohol in pneumonia had been well described in the paper. It was his custom to delay its use until it was distinctly indicated, never giving it as a routine measure except in grippe pneumonia or to old persons. When distinctly indicated, he would give it, for example, in the dose of one ounce every hour for a few times, or until a definite effect upon the pulse had been obtained, and then reduce the dose. If it were to do good at all, this effect would be secured very promptly. One symptom of pneumonia, which was often difficult to control, is violent delirium with restlessness and jactitation, and rapid pulse. Much had been said about the value of trional in such cases, and he had never hesitated to use it because he had never observed any depressing effect from it. It would often control the delirium in pneumonia even when quite severe. In addition, the bromides and codeine were useful. He hesitated always to give morphine in pneumonia, and when he did use it, it was in very small doses—not more than one-eighth of a grain. Last winter he had seen a case nearly rendered fatal by a physician giving the patient one-fourth of a grain. The same might be said regarding hyoscin, but in alcoholic cases it was difficult to get along without it. It should be used cautiously, not more than $^1/_{100}$ of a grain as the initial dose. He had not bled patients with pneumonia, for one could not tell how long a pneumonia patient would remain sthenic. He did believe, however, in the use of saline infusions in both pneumonia and typhoid fever—indeed, in almost any severe toxic condition in which the patient is overwhelmed with a systemic poison. Intravenous infusion or hypodermoclysis would often accomplish much in extremely severe cases of pneumonia. It was difficult to explain how the saline infusion acts. Possibly it dilutes the toxin in the blood, or acts by improving the arterial tension; at any rate, when the patient is *in extremis* it is a very serviceable remedy and often succeeds when everything else fails. He fully concurred with what had been said in the paper regarding the doubtful value of serumtherapy. Twenty or thirty favorable cases would be reported at times and then nothing further would be heard about them. The extremely variable character of this disease and the danger of drawing conclusions from a comparatively small number of cases should never be forgotten. It was a curious fact that, despite the various methods of treatment employed in hospitals for many years past, the mortality had remained just about the same.

Dr. John Winters Brannan said he thought he could best contribute to the discussion by relating his experience with a method of treatment with which most of the members of the Society were probably not familiar. Four or five years ago Dr. S. O. Vanderpoel had called his attention to an article in the "Medical Record" by a Dr. MacArtney on a new method of treating pneumonia and had asked him to give it a trial. The writer of this article had evidently had a large experience, his argument was scientific and his results had been very good. He stated that before using this treatment his mortality-rate had been about 16 per cent., whereas since adopting this plan in 120 cases there had been only two fatal cases, and they had been extremely severe types of the disease. A number of the patients had been elderly, and others had followed whooping-cough or measles. Dr. Brannan said that he had tried the treatment in 1897 and had carried it out to the letter. The idea was that in pneumonia there is a chill with internal congestion, and if the blood could be drawn again to the surface of the body, benefit would follow. Dr. MacArtney had endeavored to do this by prolonged diaphoresis. His plan was to take several hot bricks, dip them in hot water, cover them with cloths and put them around the patient, who is then covered up with blankets and kept in a profuse perspiration for from four to forty-eight hours according to the effect. The statement was that the temperature would soon fall to normal and the patient would have practically gone through the crisis, although the physical signs might not have changed. Sixty-seven of Dr. MacArtney's cases were aborted. A large proportion had been seen early, with the result that they had a normal temperature, freedom from pain and cough, and easy respiration in a few hours; others yielded only after two days of sweating and a mercurial purge. Dr. Brannan exhibited the charts and narrated histories of five cases in which this method had been tried by him. The first patient was a youth of eighteen, of good physique, but of alcoholic habits. The hot bricks had been applied on the fifth day of the disease, the day of his admission to the hospital, and had been continued for forty-eight hours; then, without any warning, the body temperature, which had been 104° or 105° F., suddenly rose to 109.8° F. Two hours before this the patient had been perspiring profusely and had then suddenly ceased to perspire. With the great rise of temperature he had become unconscious. The pulse at this time had been 140 or over. The bricks were taken away and he was given an ice bath with 25 per cent. alcohol for forty minutes. Toward the end of the bath the boy had had a convulsion; two minutes later he had become rational, and after this recovery had been uninterrupted. The second case was like the first, except that the bricks had been used for only two hours. Then the temperature had risen from 101° to 108°, when the treatment had been discontinued. This patient also had recovered. In the third case, the bricks had been used for three hours and the temperature had risen to 108°, with a coresponding rise in the pulse. After the bricks had been removed the temperature had come down to 102°, had reached the normal in a few days, and the patient had eventually recovered. In the fourth case, the bricks had been kept up for twenty-four hours, when the temperature had reached 107° F. and the pulse 144, though the respirations had not been materially affected. As soon as the bricks had been removed the temperature had fallen to 101° F. without cold sponging. In another day the temperature had risen again, and the patient died. In the fifth case the temperature had risen to 106° F. after eight hours' use of the bricks, but had come down to 99.6° F. afterward and the patient had recovered. In this case it is recorded in the clinical notes that the patient perspired profusely during the application of the bricks, and became restless and delirious, and the pulse became weak as well as rapid. It was at least comforting, the speaker said, to know that persons could have these very high temperatures and still recover. His experience was apparently another instance of good results being often obtained only by the originator of a new method of treatment. It is true that four of the five patients recovered, but it would seem that this was in spite of the treatment and not in consequence of it. In every case the temperature rose even while the patient was sweating, and at the same time the general condition became so alarming that energetic measures were necessary to restore the patient.

Dr. Alexander Lambert said that he, too, had been favorably impressed with the article of Dr. MacArtney. The cases just reported were good examples of heat stroke added to pneumonia.

Dr. R. J. Carlisle spoke of the treatment employed on the Third Division of Bellevue Hospital. He said that there the patient and not the disease is treated. Alcohol is not given unless distinctly indicated. To combat the fever the patient is kept in a cold pack. Digitalis is used sparingly and strychnine is used in small doses—about $^1/_{60}$ of a grain every four hours. For delirium and for the relief of insomnia, codeine is given the preference, though occasionally morphine is used in very small doses.

Dr. N. E. Brill said that it was evident from the paper and the discussion that one should be chiefly guided in the treatment by the indications imparted to the finger on the pulse and by the information obtained from the application of the stethoscope over the pulmonary artery. In spite of anything that can be done many patients with pneumonia will die.

Dr. Alexander Lambert said that he had investigated the serum treatment of pneumonia in twelve cases seen in the hospital. They had been taken just as they had been admitted to the hospital, regardless of the type presented. The action of the serum in all of them had been different from that reported by other observers in that there had been absolutely no change in the number of the leucocytes. The serum itself had been procured from a horse, the germ used being the pneumococcus obtained from the sputum of a pneumonia patient. After having been passed through 400 rabbits, one-twenty-millionth of a cubic centimeter had been used, and when injected into a rabbit it had caused the death of the animal in from thirty-six hours to four days. The dose that he had used for testing the serum had been $^1/_{1000}$ c.c. If the germ were injected behind the ear, and the injections of the serum were made in the leg of the rabbit, from 1 to 3 c.c. would be required to protect. It was evidently not an antitoxic serum, but a form of bactericidal serum. The bactericidal sera differ from the normal sera in that they possess an immune body. The substances which destroy the bacteria in the blood or the red cells in the blood when one blood is injected into another are composed of two definite substances, the immune body and the alexin or intermediary body. Immunization does not increase the alexin, but does enormously increase the immune body. The pneumococcus serum contains an enormous amount of this immune proteid. It gives all the reactions of globulin, but beyond this we know nothing. When this is injected into the blood it circulates through the lungs. In some patients who had, at the time of the injection, a definite pneumococcus septicemia, as proved by examination of the blood drawn from the vein, these pneumococci disappeared after the injection of the serum, and the patient recovered. This fact had led Dr. Lambert to think that it might be useful to use the serum in combating the pneumococcus septicemia occurring just before a fatal termination. By injecting the serum into the blood one introduces the immune body. It had been recently found that in typhoid fever the alexins were absent. In the use of typhoid serum the normal alexin is used up, and hence the desired action could not take place. Whether the pneumococcus serum failed to act for this reason or not he could not say, but in some patients it had had absolutely no more effect than water. In other cases the temperature had been reduced and had been kept down about two degrees, and the pulse had remained ten or twelve beats per minute lower. Three of the patients who recovered had been extremly bad alcoholic cases. One had had a right upper lobe pneumonia, which had involved successively the entire surface of both lungs. The serum in the blood could not affect the exudate which is in the outer space of the lungs—in other words, the serum was acting in closed tubes upon what was practically out-of-doors. Those who had spoken about the use of strychnine and glonoin had not stated whether they gave it by mouth or hypodermically. It seemed to him there was a great difference between these two methods of administration. The remedies would act surely and accurately when given hypodermically, while they would often fail to act satisfactorily if given by the mouth. Of course, in hospital practice the quantity of alcohol administered was enormously larger than in private practice, simply because most of the patients were accustomed to use large quantities of alcohol. This seemed to him the only reason why alcohol, which is a poison, acted so beneficially. He had found that alcoholic cases with intense delirium were very much benefited by the bed-bath and sprinkling the body surface with tepid water. This would often invoke sleep. He agreed with Dr. Thompson that trional is one of the best drugs to use for controlling the delirium of pneumonia.

Dr. Nammack closed the discussion. He said that he had not made mention in his paper of inhalations in the treatment of pneumonia, although during the first ten years of his medical experience he had been associated with a physician who believed firmly in their use. They had continued to use inhalations for a long time, until a physiologist had proved conclusively that the substances inhaled go no further than the primary division of the bronchi. However, two years ago he had treated some cases with heated oxygen, and one or two desperate cases had recovered. For a time he had thought there might be something in the claim that by heating the oxygen its diffusibility is increased. Another physician had subsequently told him that he had experimented upon a dog with superheated air, and had proved that the heating of the air or gas amounted practically to very little. He would congratulate Dr. Brannan on his courage in trying the hot bricks in four cases after the first case had developed a temperature of 109° F. As a rule, in private practice he administered strychnine and glonoin by the mouth, but he thought they act better when given hypodermically. The temperature in pneumonia and in acute infections generally was not the bugbear it was once thought to be, though, of course, this remark did not apply to hyperpyrexia. Among the poor, and in ill-ventilated apartments it was extremely useful to open the windows and give plenty of fresh air. The remarkable results reported by Newall among negroes treated in open cabins were more probably attributable to the free access of fresh air than to his very free use of strychnine.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 16, 1902.

The Vice-President, Hermann Knapp, M.D., in the Chair.

The scientific business of the evening consisted of a discussion on the subject of infant-feeding, opened by Dr. Joseph S. Winters.

Iron in Infant Food.—Dr. Winters said that milk is a very complete food for infants with the single fault that it is poor in iron. This is the reason why the infant is born with a much higher percentage of iron in its tissues than is normal to the adult. The iron is contained especially in the liver, from which Nature draws her stores for use in the important physiological functions in which it is concerned. This

supply of iron becomes exhausted, however, before the end of the first year of life and unless something is added to milk for the feeding of the infant the child becomes anemic. Cereals contain an important amount of iron in a readily assimilable form and consequently it is these that must be added to the infant's food in order to make it complete for nutrition. Oatmeal is the best of the cereals for this purpose in its general composition, as it contains more iron by weight than does beef. Oatmeal has certain objectionable qualities, one of them being the presence of a considerable amount of indigestible cellulose, but this can be removed by straining, and the oatmeal soup thus made becomes an ideal element for infant-feeding. In summer barley may be employed, because it seems to have less tendency to produce disturbances of the gastro-intestinal tract, though barley is poorer in iron and in fat than is oatmeal. The yoke of egg contains a large amount of nuclein—a very important substance for nutrition; it contains especially considerable amounts of phosphorus and iron, present in the form of very soluble organic compounds readily assimilable even by the infant organism. Besides this the yolks of eggs are rich in lime-salts and fat. The addition of a certain amount of egg to the diet of children should be begun shortly after nursing ceases to provide the main portion of the nourishment. A dry crust should be given the infant about twice a day after it begins to develop its teeth. The exercise of the masticatory muscles thus induced is excellent for their development, for children's jaws may fail of their proper development if mastication is not encouraged. Do not advise, as is so often the case, that infant food shall be always strained or chopped or minced; this deprives the infant of one of its best forms of exercise, that of chewing. The chewing of crusts, moreover, develops the gums and leads to the proper extrusion of the teeth, in additon to serving to keep the mouth clean. It must be borne in mind that the metabolism of nutrition in adults has for its only purpose the conservation of the individual in his present state. It provides only for passing needs. The metabolism of the child is meant to provide material to be stored for future use and is meant also to subserve the purposes of constant development and growth. The earthly salts are not needed by the adult, but they are indispensable in the child. Fat is of very little use to the adult except to provide heat, but it is a tissue builder in the child. The use of carbohydrates is scarcely necessary for the adult, while their consumption by the child serves to shield the proteids from absorption, and so leaves plenty of proteid material for the development of the organism.

Classes of Food.—There are five general classes of food, the nitrogenous, the fatty, the carbohydrate, minerals and water. All five kinds of food are needed in the child. Only the nitrogenous, the mineral and water are indispensable to the adult. Proteid material must be supplied for the constant growth of muscle and also to make up for the loss due to the constant activity of the child. This is the most important ingredient in the child's food and its absence leads to the stunting of the infant organism and the pallid state so familiar to the medical attendant on children. The phosphates are particularly necessary for new growth. All the cells of the body contain salts of phosphate. The nerves and the bones require them in especially large amounts. They are important also for the blood. It is not enough, however, simply to supply the phosphates as mineral salts; they must be given as organic compounds in forms in which they can be readily assimilated by the growing organism. This same thing is true of other organic salts. Scurvy occurs in children fed on heated milk because the heat has caused the breaking up of the organic salts so important for the child's tissues and they are present in the food in forms in which they cannot readily be assimilated. Not infrequently when scorbutic tendencies become manifest, the physician suggests that meat juice or scraped meat should be given to the child; these are mainly composed of the salts of the meat, they are very stimulant and serve only to irritate the nervous system falsely into manifestations of health that are really but lessening its vitality. Fat is an extremely important ingredient of infant food, it is especially needed in bone formation and, of course, the bone skeleton is constantly growing. The bone marrow is most important in the formation of blood. The supply of a proper amount of fat, then, is indispensable. The child of five requires half as much fat as an adult. The important question in the feeding of children is, When shall animal food other than milk and eggs be given? Meat is four times as nitrogenous as milk and contains twice as much nitrogen as farinaceous foods. A very large proportion of the nitrogen of meat, however, consists of extractives; these substances are not tissue-builders, but are only nerve stimulants. For the purposes of growth, then, vegetable proteids are just as valuable as meat. The nitrogen obtained from vegetables, besides, is free from admixture with the extractive crystalline substances which are so harmful. Meat is simply a stimulant and as such is not good for the child. Besides, the use of meat with its piquant flavors creates a distaste for cereals and milk and fat. The use of meat is as surely degenerative in its effect as alcohol. Tissue-building depends on alkaline products. All the tissues of the organism have an alkaline reaction. In the digestion of meat acids are formed and the absorption of these acids disturbs all cellular metabolism in the infantile and sensitive organism.

Vegetable Iron.—There is a distinct relation between the coloring matter of vegetables and the coloring matter of blood. Many years ago Bunge showed that iron occurred in normal physiological conditions in vegetables and could more easily be absorbed from them than from any other substances. Most of the green or red or yellow vegetables have an iron organic coloring matter in notable amount. The present teaching to give beef juice in anemic conditions is an unfortunate error. Undoubtedly many of the nervous diseases which have become so familiar in recent years in children are due to an excess of meat in the diet. The increase of such afflictions as chorea, petit mal, night terrors, laryngismus stridulus, is due to the irritative condition of the nervous system thus induced. Undoubtedly much of the irritability and the peevishness of modern children, even when no actual nerve disease exists, is due to too early allowance of meat in the diet. Meat should not be given before the child has completed its second year and then not more than half an ounce. This should not be allowed oftener than every second day until the child has reached its fifth or sixth year. The increase of weight and muscles that occurs as a consequence of the consumption of meat is readily lost. This is a common and well-recognized clinical observation. The increase of weight that comes as the result of the use of farinaceous food is much more durable. This can be readily understood when the solidity of the tissues of country children and their capacity for withstanding disease are recalled.

Forcing on Meat.—Dr. Milton Yale said that Dr. Winters' conclusions were also his own. It is deleterious for any child to be forced on meat. Many of the children of the better classes become gouty and arthritic very early in life as a consequence of the early consumption of meat in too large amounts. Very little

normal development is allowed to these children. All the exercise that they have is a personally conducted walk with their nurses in which even their volition as to what form of exercise they shall take is of very little natural benefit. Such children, as the result of meat stimulation, learn to refuse the more healthy food materials that would be proper for them. The use of the squeezed juice of steak is an especial mistake and its stimulant effect is such that Dr. Yale is accustomed to speak of it as the child's cocktail. The kitchen is really at fault in many of these cases; it is much more easy to prepare squeezed beef-juice than the vegetable foods that would be much more suitable. Personally, Dr. Yale finds it of extreme advantage to make friends with the cook and to make suggestions with regard to the preparation of food that will be of practical service. Childrens' meals are apt to be neglected in the cooking because prepared before or after regular meals in the kitchen and because all the culinary arrangements are made with the idea of serving the adults of the household. The cook in the household plays an important rôle in the feeding of the children. Frequently, though she may know perfectly well how to prepare food for adults, she is inexperienced in what is proper for children; yet it is on her that the preparation of the child's food ultimately falls. Children like the piquant taste of meat preparations, and so are prone to get more of these than is good for them. As a rule the mother does not wish to disturb the household arrangements below stairs and so the doctor must prove the intermediary. It is good for the doctor to know his cook-book and for the cook to know the doctor.

Country Life.—Dr. Dorning said that he could only emphasize some of the good points made by Dr. Winters. It is a very favorable thing for children to be brought up in the country. Outdoor fresh air in the country gives a relish and enables children to take more food, while the country tendency is to give them the simpler foods. The present tendency to give meat juice early in infant life must be deprecated. It is no unusual thing to find that at three months of age the child is taking half an ounce to an ounce of meat-juice several times a day. No meat should be given until the third year is nearly reached. The child does not need its stimulant effect and the nutrition it supplies does not justify its use. It is not enough to give as food only the chemical substances that are necessary to support life. They must be there in an assimilable form. Charcoal and sea-salt and water actually contain all the chemical ingredients that support life. Needless to say they are not ideal food materials. The organism must have the chemical ingredients necessary in the form of organic combinations that can be used for metabolic purposes. Whole wheat should be given rather than the fine milled wheat which lacks so many important ingredients that form the basis of ordinary flour as at present supplied.

Prophylaxis of Disease.—Dr. Southworth said that the question of child-feeding is especially important as regards the prevention of disease. Children's ill health is often due to poor nutrition. Lowered vital resistance because of this allows them to contract various infectious diseases. Well-nourished children escape illness. Nurslings having an abundance of ideal food for their age practically always escape infectious diseases. The transition period of a child's life, when it passes from milk to a mixed diet, is especially dangerous with regard to the contraction of various ailments.

Milk as Food Basis.—Milk must form the basis of infant food until the third year. This must be impressed upon parents for they are liable to neglect it. If children refuse to drink milk in the ordinary way from a cup, it is even advisable to prolong the use of the bottle for some time. During the latter part of the nursing period cereals must be introduced into the food, at first being used to dilute the milk. The transition period becomes less dangerous under these circumstances.

A Good Word for Beef-Juice.—Dr. Southworth would not condemn beef-juice as freely as most of the other speakers of the evening. He believes that it is an excellent tonic and a thoroughly stimulant hematogen. Pale children, weak and delicate, who are not able to obtain sufficient nourishment from the digestion of vegetable material, are often able to obtain their nutrition better from meat than in any other way. Of course, too much must not be used and it is evidently the abuse of meat-juice that has led to all the serious objection to it. During the second summer particularly, when, owing to the drain on the system of teething and the digestive disturbances of the transition period, there are special calls upon the vitality of the child, meat-juice as a nutritive stimulant makes an excellent addition to the dietary. It must not be given up entirely, then, because it happens at times to be used irrationally by those who do not realize its proper limitations.

Infantile Eye Diseases.—Dr. Bates said that many of the eye diseases of children are obstinate to treatment, except under proper diet. Scrofulous conditions of the eye, eczema and phlyctenulæ must be treated by improvement of the general condition first of all. In many of these cases, the ordinary milk and carbohydrate diet will fail to build the child up properly. Dr. Bates recently had a case under observation in which the patient failed to get better under a mixed diet in the city and grew worse in the country on an exclusive milk diet. When given cod-liver oil, however, with an abundance of meat-juice, improvement set in almost at once. In the anemic conjunctivitis of children that is so often accompanied by tendency to nose bleed, meat-juice is an important stimulant nutritive that is actually remedial in effect.

Return to Nature.—Dr. Elmer Lee said that the secret of good feeding for infants consists in a return to organic nature. The dividing of nature's units of food material reduces their value. Only part of the wheat is ground up into the modern flour and so some of the most nutritive portions of the cereal fail to get into the bread. Under the present system, children are overfed, but undernourished. The animals live on cereals and vegetables and convert them into their tissues, but in so doing exhaust a part of the material in the cereals and grass. Meat is the poorest and the dearest of foods. It costs four times as much and goes only one-third as far as does wheat, for instance. The human body is a storage cell. The ingredients that go to make it up are the battery fluid. The latest storage battery that promises to be the most successful has an alkaline reaction; all the old storage batteries had acid reaction. All human tissues are alkaline, yet they have been treated with meat, which has an acid reaction.

Prepared Foods.—In closing the discussion Dr. Winters said that the chemical composition of food, as is well known, by no means represents its nutritive value. There are many prepared foods on the market, but practically all of them are founded on the idea that certain chemical ingredients, without regard to their origin, may become nutritive portions of infant food. All artificial foods are prepared on this false notion. Every one of them should be discarded, because in their preparation organic combinations are broken up and the material is present in a form in which it is not readily assimilated, especially by the infant organism. As a matter of fact, food materials, treated as are those for the artificial foods, are deprived

of every bit of nutritive value. It would be very easy to recognize this fact, only for the conditions in which they are used. Clinical deception is perpetuated because these foods are used in combination with milk. The other ingredients are worthless, or of very little nutritive value, but the milk serves to keep up the infant nutrition to a certain extent. In Dr. Winters' experience the use of whole wheat is a common source of digestive disturbance in the children of better families in our cities. The child's stomach does not seem capable of digesting the coarser materials of flour that are usually thrown out in making the finer flour. Dr. Winters has had a recent experience in which a child fed on whole wheat and suffering from severe digestive disturbance and malnutrition for a long time got well without drugs when the food material containing so much cellulose and irritant indigestible material was removed from the dietary. Too much can not be said against the abuse of meat-juice in children. Dr. Winters has seen anemia develop hundreds of times as the result of the use of meat-juice in place of one of the feedings, as is so often advised now. There is no surer or more frequent cause of anemia in children on Manhattan Island than the use of meat-juice. The sooner its employment is discouraged under the age of two years, the better it will be for the health of large numbers of children.

NEW YORK ACADEMY OF MEDICINE.

Section on General Medicine.

Stated Meeting, Held January 21, 1902.

The Secretary, James N. West, M.D., in the Chair.

Ergot in Graves' Disease.—The paper of the evening on ergot in exophthalmic goiter was read by Dr. Van Sanvoord. Dr. Van Sanvoord has employed this remedy in a number of cases; he reported good effects from its use before and now has every reason to think that it is very beneficial in the symptomatic treatment of the disease. He asks that other observers try the remedy and report their results. It would seem that a therapeutic advance in the treatment of these cases, usually so obstinate, may thus be effected.

Distance Cardiac Murmur.—Dr. Louis Faugère Bishop presented a patient with a loud-beating heart-murmur that could be heard at some distance from the chest-wall. The patient, a colored woman of about forty, suffered four years ago, from a severe fright; afterward she developed cardiac symptoms; these continued for some time and she came to the Colored Hospital, where it was found that a loud murmur, systolic in time, was audible for some distance from the chest-wall. The patent has been conscious of this murmur herself for some time. She has no very severe symptoms from her cardiac affection and continues to be reasonably comfortable.

Myocarditis.—Dr. Bishop presented two cases of myocarditis. In each of them a distinct sign of beginning cardiac incompetency was tenderness below the xiphoid cartilage. The patients were able to do a certain amount of work, after intervals of protracted rest, but then began to have cardiac symptoms. One of the most significant warnings that they were overworking their hearts was the occurrence of this tenderness, just below the lower end of the sternum. In the male patient particularly, this extended somewhat from the median line toward the right and was evidently due to some congestion of the liver.

Dilatation of the Heart.—Dr. Bishop presented a patient suffering from great dilatation of the heart, whose cardiac incompetency has been quite marked. He is a scene-shifter who suffered from rheumatic valvulitis when quite young; his occupation required so much rushing around that he developed an acute dilatation of the heart. There was a peristaltic pulsation all over the precardium and a distinct gallop rhythm. General anasarca was present and the liver was enormously swollen and quite tender. Dr. Weber, the house surgeon, found some good digitalis-leaves at a wholesale drug-house and made a home infusion of digitalis, which was freely given; the man passed 200 ounces of urine the first day, 150 ounces the second day, and 100 ounces the third day. Under this treatment the anasarca rapidly disappeared. The result shows the effect of really good digitalis.

Musical Murmurs.—Dr. Burt said he had met with a number of these murmurs that could be heard some distance from the chest-wall. In one case he could hear it for six inches; in another he had been able to hear it for a distance of two feet. By a strange coincidence this former case of distance murmur followed immediately upon a fright; the patient had noticed it himself and came to tell of the music-box in his chest; it had been noticed also by his wife. Under rest and heart tonics it decreased and gradually disappeared. The patient was, however, a dispensary patient and the present condition is unknown.

Bovine Heart.—Dr. Burt presented a patient with an immensely enlarged heart. The condition of dilated hypertrophy is very extensive, so that the outer border of the heart can be felt as it rises in pulsation against the ribs, three inches at least outside of the nipple line. The immense size of the heart can be judged from this, since it dips back under the lung and only a portion of the anterior surface comes against the precardium.

Aneurism of Aortic Arch.—In this same case there is a large aneurism of the ascending portion of the arch of the aorta. There is a distinct thrill and bruit and an expansile pulsation. The most interesting point about the case is that the history seems to indicate that the cardiac condition and probably the aneurism also date back for twenty years. Both conditions have become stationary and neither of them produce very serious symptoms. The dulness to percussion shows the outline of the large aneurism and this has also been seen by means of the X-ray. Dr. Burt presented an X-ray picture of the interthoracic condition.

Tricuspid Regurgitation.—Dr. Burt presented a case of leaking at the tricuspid valve with expansile pulsation of the liver. The patient gives a history of excessive beer drinking and when he came to the hospital was suffering from an immense ascites. His liver was found to be considerably enlarged, though this grew less in size under rest and cardiac tonics. The heaving impulse in the hepatic region is evidently due to tricuspid regurgitation into the liver. This impulse can be felt very plainly even when the patient is standing up and is at once apparent when he is lying down. In this case mitral regurgitation accompanies the tricuspid regurgitation; the subjective symptoms are not very serious. Dr. Burt believes that the removal of the fluid somewhat slowly from the abdomen in ascites favors its non-recurrence. It gives no guarantee, however, against the return of the fluid. When the old Dieulafoy aspirator was used, and it took nearly a day to remove a large amount of ascitic fluid, patients still had regular reaccumulations of the ascitic fluid.

Heart Lesion and Prolonged Life.—Dr. James K. Crook presented a patient whom he had presented to the New York State Medical Society at its meeting five years ago. This patient has suffered from mitral leakage since 1864. In January of that year he suffered from articular rheumatism, being at that time sixteen years of age. In April of the same year, he suffered

from cardiac symptoms and the attending physician told him that he had a mitral lesion. He improved somewhat, but as his cardiac symptoms continued he consulted Dr. Flint of New York who assured him that his physician's diagnosis was correct and that he had a mitral cardiac lesion. Since then he has come under the care of more than half a dozen well-known New York physicians, all of whom assured him of the existence of a heart lesion and most of them gave an unfavorable prognosis. When presented to the New York State Medical Society in 1897 he was in excellent general condition, suffering from no subjective symptom, able to continue his occupation and only troubled occasionally by digestive disturbances. At the present time this very satisfactory subjective state continues. He has suffered from mitral regurgitation for thirty-eight years and there is at the present time a systolic murmur at the apex of his heart which is slightly transmitted toward the left. The chief interest of the case is, of course, the long continuance of his condition without serious symptoms. It is very evident that there is a better outlook in these cases of mitral regurgitation than has usually been supposed. Insurance companies are coming to recognize this fact and to modify the unfavorable prognosis on which they entirely refuse these cases.

Mitral Regurgitation for Forty-six Years.—Dr. James J. Walsh said that he had seen a case in Vienna in which the history of mitral incompetency extended over forty-six years. When seen the patient was approaching his seventieth year and over forty-six years before had been told by Skoda that he was suffering from mitral regurgitation as the result of rheumatism. His rheumatism occurred some three years before his consultation with Skoda so that it seems probable that he had lived for nearly or quite fifty years with a mitral lesion that gave a distinct systolic murmur at the apex. During this long life he had very few subjective symptoms and his occupation as a shoemaker had not proved burdensome at any time.

Good Prognosis.—Dr. Burt said that the good prognosis of cardiac lesions is not confined to the mitral valve and that even aortic insufficiency may also exist for long periods without giving serious symptoms. He had a patient under his observation some time ago suffering from aortic insufficiency. This lesion first manifested itself forty-five years ago. The man had gone through the Civil War and afterward remade his fortune, which had been lost by the fall of the Confederacy. He became the lawyer for the Plant system of railroads, so that he had accomplished plenty of work and yet had suffered very little from his heart. Occasionally, at times of overstrain, there were symptoms of cardiac incompetency and stimulants and heart tonics were needed. He died suddenly about two years ago as the result of his heart lesion. Dr. Burt said that the best sign that the prognosis of heart lesions must not be as unfavorable as formerly is found in the fact that such patients so often outlive the physicians who make the bad prognosis. The insurance companies are not so prone absolutely to refuse heart cases as before, and arrangements are being made by which sufferers from cardiac lesions can be accepted under modified conditions. This is as it should be for the prognosis in cardiac cases is not absolutely, but only relatively unfavorable. The future of the patient depends upon the condition of his heart muscles and its ability to compensate for the mechanical disadvantage of the valvular lesion.

Musical Distance Murmur.—Dr. Alfred Meyer presented a patient in whom a distinct musical murmur can be heard in a quiet room some distance from his chest-wall. The man is thirty-three years of age, has a negative family history and never had any rheumatism. Three years ago, when he came under observation because of symptomatic cardiac incompetency, he gave a history of smoking ten cigarettes a day and of taking considerable alcohol. His alcoholic history was carefully inquired into by Dr. Meyer himself in order to be sure of the details. It is often the custom to say no alcoholic history or moderate alcoholic history, without sufficient inquiry. The man confesses to having taken four drinks of whisky a day, one of them before breakfast on an empty stomach. This seems to oe an important detail in the alcoholic history, since the absorption of the alcohol is so rapid at such times. The patient first heard the noises in his own chest and then his wife heard them. Shortly after this, as the result of some anginoid symptoms, he came to the hospital, where it was found that there was a musical diastolic murmur best heard in the aortic region to the left of the sternum, but also audible all the way down the sternum and in the back as low as the sacrum. The man improved considerably under rest and heart tonics, and has been able to do some work without serious discomfort.

Hearing Distance Murmur.—In order to hear distance murmurs well it is important that the room should be extremely quiet and the ear should become accustomed to the note of the murmur by listening to it with a stethoscope until it is fairly impressed upon the auditory apparatus. There is no doubt that under these circumstances the murmur is heard better and at a greater distance from the chest. It is not that the psychological element adds to the distance by the imagination of sound, but that the physical auditory apparatus is rendered more capable of hearing.

Distance Murmur.—Distance murmurs are very rare. The explanation of the murmur that has been given as the result of autopsies in a certain number of these cases is that there is a dilation of the orifice at which the murmur occurs, in this case the aortic ring, and that as a consequence the valves do not completely close up the orifice and the regurgitating blood flowing over the tightly stretched edges of the valve leaflets produces vibrations and consequently the musical sounds. The mechanism is thus somewhat the same as the air going over the vocal cords and producing sounds. In one reported case there was some thickening of the edges of the valves, but rough surfaces do not produce a musical murmur and as a rule one must conclude that there is no pathological change in the valve tissues.

Etiology.—In the present case the murmur seems to be due to a combination of alcoholism and excessive use of tobacco. All other causes of heart disease can be excluded. There is some suspicion of lues in early life, though there have never been any serious symptomatic or pathologic conditions as a result. There is an accompanying systolic murmur in this case, but this furnishes no hint to the etiology of the valvular disturbance and does not supply an explanation for the diastolic musical murmur at the same valve.

Diastolic Musical Murmur.—Dr. Burt said that this is the first diastolic musical murmur that he has ever heard. Systolic musical murmurs are rare enough, but diastolic musical murmurs are much rarer. Dr. Burt has seen only two cases with distant musical murmurs in twenty-five years' experience of heart disease. This experience has included the large number of admissions to the Bellevue Dispensary for over twenty years.

Disposal of Cardiac Cases.—Dr. Martin gave the clinical history of a case of chronic myocarditis. The patient, a woman of forty-nine, suffered from carcinoma of the breast four years ago, and the gland was

removed. There was secondary carcinoma of the lymphatics, and these were operated upon six months later. There has been no recurrence and at the present time the X-rays fail to disclose any cancerous tissue. She is suffering, however, from cardiac incompetency and has made the rounds of the hospitals. Under diet and rest with proper nursing and care she improved. As soon as dismissed from the hospital, however, and compelled to work for her living, she relapses into her former condition of cardiac incompetency and must take to her bed. Such patients cannot be kept in hospitals for a long time, because they would soon take up all the available space. What is needed is a sanitarium or home for cardiac cases. They are unfit for self-support and when out of hospitals are, unless under exceptionally good circumstances, sure to be in distress. An attempt has been made to supply hospital care and treatment by informing visiting nurse associations of the presence of such invalids in certain parts of the city and calling attention to their special need for care. It is possible that these benevolent nursing societies and college settlement visitors and those from other charity organizations might be warned in the same manner, and suggestions given as to the way in which they could be of help to such patients. Certainly at the present moment these cardiac cases present an important and, as yet, unsolved philanthropic question that demands solution in the immediate future. Charity could find no better or more deserving field for its exercise than among this class of patients.

Solution of Problem at Colored Hospital.—Dr. Bishop said that one solution of this problem was at present in actual progress at the Colored Hospital in this city. These cardiac patients are kept in the hospital wards, where, fortunately, as yet there is no lack of room for all applicants. Whenever, as the result of rest in bed, careful diet, nursing and medical care, they are well enough to work, they are allowed to help with the various duties of the hospital, and especially to do light work in the laundry. This enables the hospital to be somewhat self-supporting, yet keeps these patients under constant medical supervision, so that their condition does not become serious, and whenever symptoms supervene, they are once more put to bed. Dr. Bishop thinks that the real solution of this problem of care for cardiac patients must come in the form of an institution similar to the epileptic colony. Cardiac patients need the outdoor air and a certain amount of light farm work may not prove too exhausting for many of them. Patients themselves will not be satisfied in an institution where they have nothing to do and where they have no sense of accomplishing something for their own support. A colony seems an ideal solution of a difficult philanthropic problem and this idea must be considered first of all by those who would benefit these cardiac patients.

Good Nursing.—Dr. Burt said that the term "good nursing" has recently come to be abused. Doctors use it and imply that it is the only method of treatment for many forms of disease. The general public accepts an entirely wrong significance of the term, quite different from that intended by the physician. "Good nursing" means not only the presence of a trained nurse in charge of the case, but proper symptomatic treatment. Without the treatment of symptoms, as a rule, nursing is a failure. For symptomatic treatment a very careful, conservative physician is needed in charge of the case. When doctors use the term "good nursing," they should impress the idea that this implies good medical attendance as well as mere nursing.

Special Hospital.—Dr. Burt said that for cardiac cases there is need of a special hospital quite as much as for tuberculous cases. At the present moment the hospitals are entirely unable to provide the necessary room for the chronic cases of heart and arterial disease that are constantly under treatment. When philanthropists get through with the foolish notion that the head is the only part of the human organism that needs specially to be cared for, they may do something for the heart as well as the head. One would be tempted to think that the reading of many books was the one thing necessary in life, as if there were not quite as much harm as good done by reading. Physicians who see so much suffering in the world see many opportunities for the investment of philanthropic funds where they would do much more for humanity than they can invested in libraries.

Care of Dependents.—Dr. Alfred Meyer said that in the care of cardiac patients, as with regard to those suffering from tuberculosis, there is always the additional question of the care of those dependent upon the patients, as well as the patients themselves. This is really a therapeutic question for it may be well understood that no patient suffering from serious illness can improve consistently in health and gain strength with the knowledge that those whom he loves are suffering while he is under care. Other countries have faced this question of the care of dependents, especially as regards the question of tuberculous patients, and private charity must face it in this country.

Medical Philanthropy.—With regard to medical charity Dr. Meyer finds very promising indications of the trend of present day charity toward medical objects. It is sometimes said that medical men and their work for the poor are unappreciated by the general public; as a matter of fact, however, medical men are placed on a higher plane of consideration than are those of other professions, and while more is expected of them there is an underlying generous appreciation of their professional work that is of itself a striking compliment to professional philanthropy. Nearly every one finds it easy to say how money shall be spent for philanthropic purposes and the millionaires who have it to distribute find it a difficult problem to satisfy the many claims. True humanitarianism, however, is an especially prominent feature of the feeling of the wealthy at the beginning of the new century.

NORTH BRANCH OF THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held January 16, 1902.

The President, A. M. Eaton, M.D., in the Chair.

The Diagnostic Value of a Digital Examination in Diseases of the Rectum.—The author, Dr. H. A. Bray, dwelt at some length on the fact that the general practitioner treats diseases of the rectum too much from a symptomatic standpoint and without making local examination. Patients with rectal difficulties usually present symptoms of extreme nervousness, melancholia, sometimes with suicidal intent, pain in the rectum, digestive disturbance, disorders of the liver, etc., and very often the patient is treated for the most prominent of these symptoms without the real cause of the trouble being suspected. Several cases were cited in support of this theory; one patient had been treated by many physicians for chronic constipation. When he came under the author's observation a digital examination was made which revealed a stricture 2½ inches above the external sphincter muscle. In another case which was being treated symptomatically for constipation, local examination revealed carcinoma of the rectum situated two inches above the external sphincter muscle. The method of making the examination was given in detail and especial stress was laid upon the importance of ex-

amining the parts close to the anus, as well as those higher up in the bowel.

Operative Treatment of Hemorrhoids.—Dr. Charles F. Nassau read this paper. The different methods of procedure in operating on this condition were fully discussed and the view expressed that the ideal method of operating is to treat the hemorrhoidal area in the same manner as one would treat a varicose condition in any part of the body, thus avoiding the pain produced from unhealed ulcerating surfaces, the result of sloughing away of ligatures, or the granulating lines left by the clamp and cautery. As regards the use of escharotic injections, they were considered of no use in external piles and, although producing considerable benefit in some cases of internal hemorrhoids, the dangers attendant upon their application were such as to overbalance their merits. Local infiltration anesthesia was recommended in suitable cases, although it was thought to increase the technical difficulties of the operation. In cases having comparatively small internal hemorrhoids, stretching of the sphincter ani and careful attention to the fissures (the application of the cautery, division of the base to healthy tissue or complete excision, followed by careful suture) was recommended. In minor cases of isolated external piles, excision of the veins involved followed by careful suturing of the skin wound was recommended. The Whitehead operation, while based upon correct grounds, was considered faulty in its technical details, and, as it is also sometimes followed by stricture and even incontinence, it was not advised. For the more difficult cases the excision of the entire pile-bearing area, followed by suturing, was thought to be the most desirable procedure. This operation can be done either under local anesthesia or ether, according to the indications of the particular case. Considerable stress was laid upon the importance of general and personal hygiene following this treatment and the patient should be especially instructed to secure a daily action of the bowels.

The Diagnosis and Treatment of Carcinoma of the Rectum.—Dr. George C. Ross considered that there are five varieties of this condition, epitheliomatous, scirrhous, encephaloid, colloid, and melanotic carcinoma or sarcoma, the frequency of their occurrence being in the order named. The most common form of cancer of the rectum is the variety of epithelioma known as adenocarcinoma. The most rapidly fatal form is the sarcoma or melanotic carcinoma, which is also the most rare, only eleven cases of this variety being recorded. The importance of digital examination and inspection in all cases of local ailment of the rectum was emphasized and the author considers that in cases of doubt the administration of a local anesthetic, or even of ether, if the case indicates, is not only permissible, but demanded when necessary in order to secure a specimen of the growth for microscopical examination. Cancer more frequently occurs in old age, the percentage of cases increasing very rapidly after the age of twenty years.

Total extirpation in the early stages of the disease was considered the only hope of a cure, while in the later stages palliative measures alone can be employed. Statistics regarding the immediate mortality-rate were given and it was shown that about twenty to thirty per cent. of the cases are immediately fatal when radical measures are employed, the causes of death being peritonitis, shock and retroperitoneal infection, with resulting septicemia. There are very few reported cases in which the patients have remained perfectly well for a period of four years, and the best authorities on this subject seem to give a very unfavorable prognosis. The two principal methods used for extirpation of the diseased rectum are Kraske's operation and its modifications and one which is applicable in the female, using the route of the perineum to gain access to the bowel. This operation is claimed by those who have used it to be a very satisfactory one. In the cases in which radical treatment is not indicated, either because the disease is too far advanced or for any other reason, colostomy is the only alternative; this operation was also recommended in some instances as a preparatory measure in order to allow the patient to build up his strength before radical procedure was undertaken.

Discussion.—Dr. William L. Rodman opened the discussion and stated that he considered too much stress could not be laid upon the importance of a thorough digital examination in diseases of the rectum. In regard to the different varieties of carcinoma he considers adenocarcinoma of the rectum of most common occurrence; in his experience the scirrhous and encephaloid forms of the disease have been rare. Several instances were noted of cases which had come under his observation in which, contrary to the usual rule that carcinoma of the rectum usually proves rapidly fatal, five, ten or even twelve to fifteen years had elapsed before death, the patient in the interim remaining in fairly good general condition. If radical procedure is to be undertaken the importance of early operation was urged, and when the disease has become far advanced before surgical relief is sought colostomy is thought to be the most advisable measure, as at this time only palliation can be hoped for, and this operation seems to afford more relief than any other. With reference to the different operations in use for the removal of hemorrhoids he thought that ligation is to be preferred. The Whitehead operation makes a major procedure out of what should be a minor one. Excellent results may follow carbolic-acid injections, but the untoward results sometimes following this method more than overbalance its merits. The chief objection to the clamp and cautery seems to be the liability of hemorrhage following the operation if the stump is cut off too close. In some instances embolism, followed by sudden death, has occurred. In the ligature operation, the hemorrhage, if it occurs at all, usually occurs before the patient recovers from the influence of the anesthetic and no instances have come under his observation in which secondary hemorrhage has taken place.

Dr. E. W. Holmes urged the necessity for thorough local examination in all cases of rectal diseases and cited instances where under mistaken diagnosis, due to the physician relying wholly upon the clinical conditions present, grave errors had been made in treatment and relief by operation delayed until it was too late. Reference was made to an electric proctoscope which had been recently placed on the market and which seemed to be a very valuable instrument.

Dr. G. Betton Massey discussed at some length the different varieties of cancer and the various methods employed in their treatment. From his own experience he is inclined to favor the electric cautery. In two cases which have recently come under his observation he has used this method with very satisfactory results. He especially urged early recognition and treatment of this condition.

Dr. Mordecai Price expressed the view that the different operations performed by different surgeons for rectal disorders are due principally to the individual's familiarity with the particular operation which he prefers. Formerly he was much in favor of the Whitehead operation, but some years ago he saw a case in which the results were such as to deter him from practising it further. Since that time he has been using the clamp and cautery and has never experienced any untoward

results therewith. Regarding carcinoma of the rectum he is of the belief that there are very few, if any, cases in which it can be cured.

Dr. Lewis H. Adler considered that, notwithstanding the fact that many surgeons are opposed to operating on hemorrhoids when they are in an inflamed condition, it is better to operate at this time than to wait until the disease has made such progress that the patient is greatly weakened thereby, which will be the result in a majority of the cases, owing to the fact that when the patient is not suffering pain from the piles, he will not consent to an operation. Stress was laid upon the importance of differential diagnosis between external and internal piles and for the relief of the external variety the thermocautery was recommended. He considered the clamp and cautery superior to the ligature and believed that when this method is properly used the danger is practically nil.

Dr. Andrew J. Downes referred to the use of the ligature and also the use of the clamp and cautery and considered that one of the most essential points was to be sure not to include the skin in either the clamp or ligature, as he felt sure that this was responsible for much of the pain following either method. For the purpose of controlling hemorrhage, he recommends the electro hemostatic forceps in place of the ligature.

BOOK REVIEWS.

A Manual of Venereal and Sexual Diseases. By Wm. A. Hackett, M.B., Ph.G., M.C.P.S. (Ont.), Professor of Dermatology and Venereal Diseases, Michigan College of Medicine and Surgery, and N. E. Aronstam, M.D., Ph.G., Assistant in Chemistry and Clinical Dermatology, Michigan College of Medicine and Surgery. G. P. Engelhard & Co., Chicago.

This number of the "Standard Monograph Series" is a little volume of just 200 pages that contains an excellent résumé of the important subject of venereal and sexual diseases. It is written from a thoroughly practical standpoint and will doubtless appeal to the general practitioner. There is perhaps more significance given to the subject of non-specific urethritis than is usual in text-books at the present day, and perhaps the prognosis of treatment for acute gonorrhea is more hopeful and less dubious than is justified by actual experience. With regard to syphilis nothing is said of the question of the renewal of treatment occasionally even after the original two-year course of medication is passed. In general, however, the little book is a thoroughly commendable hand-book on its subjects.

The Medical News Pocket Formulary. By E. Quin Thornton, M.D., Demonstrator of Therapeutics, Pharmacy and Materia Medica in the Jefferson Medical College, Philadelphia. New (fourth) Edition. Lea Brothers & Co., Philadelphia and New York.

The Medical News pocket formulary is less bulky than formerly, more easily carried in the pocket, and yet contains quite as much material as before. Altogether there are seventeen hundred well-chosen prescriptions. A certain number of new formulæ have been added for the present edition. Among these may be mentioned the use of hydrogen peroxide in the obliteration of powder stains, the internal administration of urea in the treatment of lupus, the local application of guaiacol in promoting the absorption of serous exudates, the use of apomorphine as a sedative in alcoholic delirium, the local use of adrenalin as a hemostatic, and the use of organic compounds of silver and arsenic as substitutes for the more poisonous inorganic salts. There is evidently a well-directed effort made to keep this very practical little book thoroughly up to date.

The Practical Medicine Series of Year-Books. Comprising Ten Volumes on the Year's Progress in Medicine and Surgery, Issued Monthly. Vol. I. General Medicine. Edited by Frank Billings, M.S., M.D., Head of Medical Department and Dean of the Faculty of Rush Medical College, Chicago, With the Collaboration of S. C. Stanton, M.D. The Year-Book Publishers, Chicago.

Notwithstanding the many quarterlies and year-books of medicine, and the present custom of the medical magazines of furnishing their readers with abstracts of current medical literature, this new set of volumes which will go handily into the pocket promises to fill a want. The present volume includes diseases of the respiratory and circulatory organs, of the blood, kidneys, bladder and ductless glands, infectious and constitutional diseases, and the subject matter is well chosen. If all leading articles had mention in such a book it would be either too large, or useless on account of two great brevity in abstracting. Therefore, the editors have chosen only articles of special value, and have made their abstracts lucid and practical enough, so that it is unnecessary for the reader to consult the original articles. There are four good plates showing the skin lesions of smallpox and chicken-pox, and a few drawings in the text.

Venereal Diseases. A Manual for Students and Practitioners. By James R. Hayden, M.D., Chief of Clinic and Instructor in Venereal and Genito-Urinary Diseases at the College of Physicians and Surgeons (Columbia University), New York. Third Edition. Lea Brothers & Co., New York and Philadelphia.

This number of Lea Brothers' series of pocket text-books is now in its third edition. This is of itself an indicaton of the fact that the book has found a place to fill and is filling it. For general practitioners no better résumé of the subject can be found in so brief a space. In the present edition new sections on venereal vegetations and on herpes progentalis have been added. This has not increased the size of the book, however, as certain merely theoretical considerations on the history of venereal diseases and the statistics of their occurrence have been omitted. The book is concise, compact, handy and as complete as can be expected under the circumstances.

Transactions of the Twenty-Third Annual Meeting of the American Laryngological Association, Held at New Haven, Conn., May 27-29, 1901. Rooney & Otten Printing Company, New York.

This, like its predecessors in the same line, is a dignified volume of transactions, admirably edited and put into the same excellent form of its companion volumes of preceding years. The articles submitted to the Association at its annual meeting are all of the same general tone of excellence. Of special interest is the historical chapter by Dr. Jonathan Wright.

The remarkable cases of empyema of the antrum of Highmore given by Dr. Emil Mayer and the splendid illustrations of his sinus cases by Dr. J. H. Bryan are of especial interest and value. The chapter on retrograde metamorphosis of the faucial tonsil is of timely interest. Other chapters of great interest and value are devoted to intubation, reflex nasal epilepsy, nasopharyngeal fibromata and the ever-timely subject of anesthesia. In all 274 pages are filled with most valuable material.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. 80. NEW YORK, SATURDAY, MARCH 1, 1902. No. 9.

ORIGINAL ARTICLES.

SUTURING THE HEAD OF THE HUMERUS TO THE ACROMION IN OLD SUBCORACOID DISLOCATION.[1]

BY CARL BECK, M.D.,

OF NEW YORK.

THE patient, an engineer forty-three years of age, was run over a little more than six months ago and was treated by a druggist for contusion of the right shoulder until the early part of November. On November 9th, when I saw the patient for the first time, I found the shoulder much flattened and the acromion unduly prominent (Fig. 1). The joint-cavity was empty and the

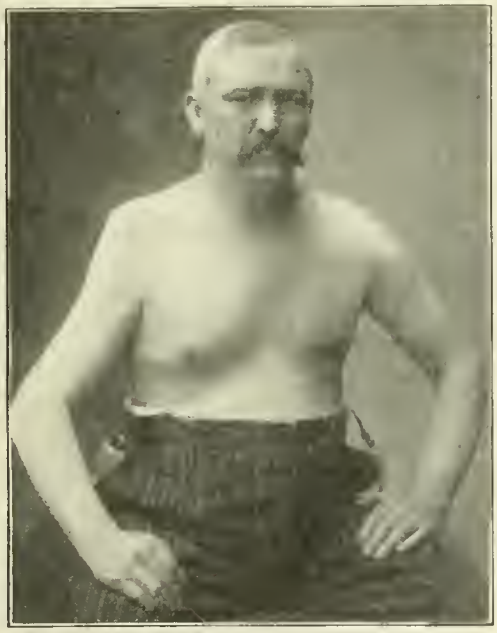

Fig. 1. Right subcoracoid dislocation.

head of the humerus could be palpated in Mohrenheim's groove. The arm was slightly shortened, the motion of the arm greatly impeded, and the patient suffered from intense periodical pain, which seemed to be dependent upon nerve-pressure.

The Roentgen rays revealed the typical signs of subcoracoid dislocation (Fig. 2). At the anterior surface of the neck of the scapula a thickened area was noticed, which made me suspect that there was a coinjury of this portion, but the skiagraph showed the bones to be intact. As the operation proved afterward, the thickened portion which might have corresponded to callus-formation was caused by the presence of frag-

ments of the glenoid capsule which had formed an irregular mass.

After various methods of reduction were tried

Fig. 3. Dislocated humerus reduced.

[1] Case presented before the Surgical Section of the Academy of Medicine, December 9, 1901.

in vain under anesthesia, a nearly semilunar incision was made which began at the acromion and running over the intertubercular sulcus was extended vertically alongside the anterior surface of the arm (Fig. 3). Thus both the joint and the acromion were exposed. After extensive and careful dissection of adhesions I succeeded in rotating the head of the humerus in its glenoid cavity. There was a pronounced tendency to forward displacement which could not be overcome by additional exposure. Therefore, I fastened the head of the humerus in the cavity by suturing it to the acromion after having drilled a hole

Fig. 4. Dislocated humerus kept in place by silver wire.

through the acromion as well as through the head of the humerus. On boring the head was found to be very soft, a fact which was also illustrated by the light shadow of the skiagraph. The skiagram (Fig. 4), taken two weeks after the operation, showed the humerus in good position. There was no reaction and the result appears to be secured. It seems to me that this procedure is far preferable to the resection of the head of the humerus, as advised by so many surgeons. No force being required, laceration of muscles, blood-vessels and nerves is easily avoided.

DIPHTHERIA; WITH SPECIAL REFERENCE TO THE SYMPTOMS AND TREATMENT.[1]

BY LAWRENCE T. ROYSTER, M.D.,
OF NORFOLK VA.;
SOMETIME INTERNE AT WILLARD PARKER HOSPITAL, NEW YORK; FORMER RESIDENT PHYSICIAN, NEW YORK INFANT ASYLUM, NEW YORK CITY AND MT., VERNON.

No one is aware, more fully than myself, of the great amount of literature on this disease which has been placed before the medical public. Many of the articles have been excellent, showing careful observation and scientific research, many more, on the other hand, have shown either knowledge born of small experience, or a total ignorance of the subject. On account of the latter I feel amply justified in offering a few thoughts suggested by a somewhat extended experience with this disease.

As my attention will be given largely to the symptoms and treatment, I will be brief in the discussion of the other phases of the subject, touching only on such points an accurate knowledge of which is necessary to a rational treatment of the disease. I will mention the pathology only incidentally.

Diphtheria is an acute, infectious and contagious disease, of which the most constant manifestation is the formation of a pseudomembranous deposit, usually on a mucous surface. There is also a toxemia accompanied by certain characteristic constitutional disturbances arising therefrom.

The etiology of diphtheria may be considered under two heads, predisposing and exciting. Under the first head, predisposing, may be placed anything which undermines the general health. Diphtheria frequently follows sore throat or exhausting diseases and conditions, being often a complication of convalescence from scarlet fever and measles. Formerly defective plumbing was considered a prominent predisposing factor. This is probably true, however, only in so far as it may cause a simple or more frequently a saprophytic angina which becomes a suitable culture-medium for the growth of the bacillus.

Naturally we find diphtheria more frequent, and in fact endemic, in closely-settled districts, but, unlike most contagious diseases, it is by no means rare in outlying and suburban localities and is sometimes found among the inhabitants of the islands of the sea. The age of selection of the germ seems to be under the tenth year, though adults are by no means exempt.

Under the second head we may place the Klebs-Loeffler bacillus as the sole exciting cause. The period of incubation is variously stated at from one to seven days. Seven days, I think, is somewhat long; one to three days being about the usual period. I know of one instance in which the incubation was less than twenty-four hours. Vomiting and convulsions, so common in the eruptive diseases, are rare, convulsions being very unusual. Even an initial chill is uncommon. There is sometimes a period of malaise, but the attention is usually called first to a difficulty in swallowing or to a pain at the angle of the jaw, or to an enlargement of the submaxillary or anterior cervical glands. The temperature ranges from 100° to 103° F., but more frequently remains nearer 100° than 103° F. The temperature is apt to be higher at first than at any other time of the disease (except in the event of complications), and, as a rule, when the patient comes under our notice the temperature is rarely over 101° F. The pulse, however, is usually very rapid from the first, showing a rapidity of absorption of toxins which is probably unequaled in any other disease. This disproportion of pulse and

[1] Read before the Norfolk (Va.) Medical Society, Nov. 12, 1901.

temperature forms one of the most valuable diagnostic features of the disease.

The most prominent local symptom, of course, is the presence of the pseudomembranous deposit, which is situated most frequently at the junction of the tonsils with the soft palate. In mild and simple cases the membrane remains in this situation, and may be so slight as to resemble strongly a follicular tonsillitis—so much so in fact that it may puzzle the most expert clinical diagnostician. The only safe method of diagnosis in such cases is the culture. Hence, the importance of an early culture in all cases in which there can possibly be any doubt. In more severe cases the membrane extends to the velum, over the whole tonsil, to the posterior pharyngeal wall, nasopharynx, nares or larynx, through the lacrymal duct to the conjunctiva of the eye. The membrane may be primary in any of these situations or may be there only by extension. The most serious localities for the formation of the membrane are the larynx, nose and eye, each of which calls for special local treatment. There is also a form of diphtheria which is characterized by a serosanguineous discharge from the nose.

I am fully aware that there is a great weight of opinion against the probability that this form is of a true diphtheritic nature. But in the light of experience with a large number of cases occurring during an epidemic, I am able to present the following evidences of its genuineness: (1) The Klebs-Loeffler bacillus (or the pseudo form or both) is always found in the discharge. (2) All the constitutional symptoms of true membranous diphtheria exist in this type. (3) It is capable of infecting others with the membranous form of the disease. (4) It is cured by antitoxin.

The odor of the breath of a patient suffering with a severe form of diphtheria is characteristic, and once smelt is never forgotten. The cervical adenitis, which is so common a symptom, rarely seen when there is a pure infection from the Klebs-Loeffler bacillius, is almost invariably seen when there is mixed infection, which is generally the rule. The enlarged glands, however, rarely suppurate.

Authorities have endeavored to distinguish between the constitutional symptoms of the pure form and those of the mixed infection, but no distinction has been made which is of diagnostic value. The mixed infections, however, are much more severe and probably play an important part in the so-called malignant cases from which arises that much dreaded condition "sepsis."

The urine frequently contains albumin, but to a much less extent than is the case in other febrile conditions, especially the eruptive fevers. Certainly I have not found it often enough to warrant its being classed as a symptom.

I mentioned the peculiar ratio between the pulse and the temperature. This is pathognomonic. A sudden change in this relation, however, portends danger. A pulse suddenly becoming slow and irregular indicates a rapidly-failing heart. Also a steady rise in temperature, which cannot otherwise be accounted for (pneumonia, etc.), usually means the setting in of the "septic condition" just mentioned and is an almost sure forerunner of death.

The more severe forms differ from the foregoing in the following particulars: There is, of course, a more extensive membrane, partly or wholly covering, as has been said, the tonsils, pharynx, nasopharynx or lining the nose. The discharge of mucus is profuse from all of these surfaces. Hemorrhage from the mucous surfaces, especially from the nose, is not uncommon and may become alarming (hemorrhagic form).

The severity of the constitutional symptoms is in direct proportion to the extent of the membrane, which may spread with exceeding rapidity, the system becoming rapidly overwhelmed by the poison until the patient is sometimes beyond hope within twenty-four hours from the first appearance of the exudate. This degree of rapidity is fortunately rare.

The symptoms, as a rule, develop gradually, progressively showing marked prostration, a rapid and feeble pulse, and usually stupor, but there may be extreme restlessness and at times even delirium. The temperature in these extreme cases is variable, ranging from normal to 105° or 106° F., sometimes in the worst cases being low and at other times high from the start. As I have mentioned before, the malignant and septic cases are usually a mixed infection with the streptococcus. In these cases it is not so uncommon to find nephritis, which, however, in itself rarely causes death.

A fatal termination of a septic case is preceded by a rapidly-failing heart and extreme prostration, neither of which improves under stimulation, disturbed respiration (aside from croup cases) and consequent cyanosis, and vomiting and diarrhea. Death from diphtheria usually results from an overcoming of the system by the toxemia (asthenia), cardiac failure, directly due to the action of the poison on the muscle (parenchymatous degeneration) and nerves (paralysis) of the heart, and from asphyxia as in croup. Of course any of the numerous complications may cause death.

Membranous Croup.—When I speak of membranous croup I refer to it only as a specific diphtheritic infection. Very rarely non-diphtheritic membranous croup has occurred, cases having been reported by several eminent and undoubted authorities. But its extreme rarity is admitted by all, hence the importance of taking no chances and of treating all cases as true diphtheria.

The development of membranous croup is usually gradual, but, unlike the spasmodic variety, steadily increases in severity. For the first day we may have little more than gradually-increasing hoarseness, the ratio between pulse and temperature not being so constant as in the other forms of the disease; but during the following twenty-four hours the breathing becomes forced, rapid and harsh, the little patient bringing into

use all the accessory muscles of respiration, the suprasternal, supraclavicular, epigastric and intercostal regions becoming depressed with each respiration; the patient becomes more and more restless until the efforts and struggles to obtain air are distressing to witness. The lips and fingers become blue, the child rapidly sinks into a half conscious condition, the violent efforts to breathe cease, the color becomes ashy, the pulse weaker and weaker, and, finally, death ensues. In the more fortunate cases under early treatment by antitoxin, these symptoms, instead of reaching the stage of unconsciousness, gradually subside in reverse order to the above. When antitoxin is not administered soon enough, relief has to be given through the use of the laryngeal tube.

By far the most frequent complication of diphtheria is bronchopneumonia, occurring in a large percentage of croup cases and especially in tracheotomy cases, thus constituting one of the chief objections to that operation. Otitis is not so frequent as in scarlet fever and measles. Pericarditis is fairly common. One of the most alarming complications and one which is sometimes very hard to control is nasal hemorrhage. Vomiting and diarrhea may be troublesome. The paralyses are the most constant of the sequelæ. The most frequent of these is the paralysis of the soft palate, causing regurgitation of food. The pharyngeal muscles are also affected, and peripheral neuritis is not at all rare in the serious cases.

Treatment.—The treatment of diphtheria may be considered under two heads, local and general. Briefly, in uncomplicated cases the local treatment consists of irrigation and the administration of antitoxin and stimulants.

Formerly, strong antiseptics, both in solution and in the form of powder, were applied to the membrane, which was then removed either mechanically or chemically. Antiseptics locally applied have been shown by careful experiments to exert their influence for so short a time as to be practically useless either in preventing the spread of the membrane or in preventing a further absorption of the toxin. In order to disinfect the membrane it would be necessary for the disinfectant to penetrate it; this it is unable to do. In order, therefore, that the disinfectant should prevent the further absorption of toxins, the membrane would have to be removed forcibly. This procedure is deemed wholly inadvisable in the light of modern scientific research, for the following reasons: The membrane is formed from within outward by a necrosis and fibrinous exudate, the direct result of the action of the bacilli, thus forming a closely-matted and tough mass of dead cells and fibrin, which acts as a barrier against the bacteria always present in the mouth. Hence, when the membrane has formed we have an intoxication only from the bacilli originally present and causing the membrane; when it is forcibly removed, however, a raw surface is left which affords a ready entrance to new bacteria and their toxins and which with the pouring out of fibrin, which at once takes place, again forms a fresh culture-medium for these bacilli and causes a new infection. On the other hand, Nature separates the membrane by forming a new mucous membrane beneath it as the body overcomes the poison, thus protecting it from a fresh infection. Then, as the false membrane peels up, it gives a direct indication of improvement and forms one of the most valuable guides to the further treatment. From this we see that the poison must be combated from within and not locally; hence the modern treatment by antitoxin and stimulation.

Nothing remains to-day of local treatment save irrigation systematically performed with hot salt solution. The object of this is two-fold: First, to remove the loose pieces of detached membrane as it exfoliates in the process of repair; second, the heat of the irrigating fluid greatly alleviates the accompanying inflammation of the pharynx and reduces the consequent swelling.

In order to irrigate, the child should be wrapped, from the shoulders down, in a sheet which is pinned closely so as to render the patient entirely helpless. The child is then placed on its back on a table, with the head turned to one side, a rubber sheet is placed around the shoulders and a Kelly pad beneath the head. The left hand of the operator is placed on the child's head in order to keep it still and the long nozzle of a fountain syringe is introduced into the mouth (along the inner surface of the jaw if necessary to open the mouth by force) and the irrigation performed intermittently. This is done in order to give the patient an opportunity to spit out the water, thus avoiding choking. The only objection that has been raised to irrigation is that it sometimes causes middle-ear disease. But of this there is no proof. In nasal cases the same method is used except that we employ the short blunt tip of the syringe. When the membrane is so large as to plug the nose we have recourse to the hand bulb syringe. The temperature of the water used should be from 110° to 130° F., depending on the local pain and swelling. In urgent cases irrigation may be employed every hour for some time, but usually three to four times a day is sufficient.

In no disease have we a more certain specific than in diphtheria. No unprejudiced observer can compare the statistics of the present day, taken at random from any large hospital, with those of the pre-antitoxin days and not be convinced of the efficacy of antitoxin. Two important factors are necessary to the successful treatment of diphtheria—an early diagnosis and a sufficiently large dose of antitoxin. The first of these must be secured by a careful watch over all sore throats and hoarse voices and an early appeal to the culture. As regards the second factor, the initial dose of antitoxin should rarely be less than 2,000 units, and in moderate cases, if there be not marked improvement within twenty-four hours, this dose may be repeated without injury. In more severe cases my initial dose is from 3,000 units in children to 4,000 or 5,000 in adults. It

has been demonstrated that antitoxin in large doses has no bad effect and it is therefore better to administer a large quantity than to hesitate through timidity and thereby attain no results. Usually the improvement begins to be manifest within thirty-six hours after the administration of the first dose. The first indication of improvement is shown in the arrest of a spreading membrane, and almost at once the edges of the exudate begin to exfoliate, the constitutional symptoms subside, the temperature, if high, drops and the patient's condition is generally improved. The pulse is somewhat slower to improve, but this improvement is gradual and steady. When the patient is specially restless morphine is the drug to be relied upon.

Stimulation, next to antitoxin, is the most important part of the treatment. Whisky I think is the best agent, certainly in the earlier stages of the disease; later, and particularly when there are paralyses, strychnine is of value. A rapid and weak, or an intermittent pulse calls for immediate action; absolute rest secured if necessary by morphine and active stimulation are required. Forced nutrition may be necessary, as the patient frequently refuses all food.

The various complications of the disease are treated as if they were primary conditions. Otitis media calls for early incision of the drum, but both this and the eye infection call for the aid of a specialist.

In the treatment of croup so much depends on the exercise of careful judgment and a wide experience with the condition that it is difficult to make any definite statement. An early diagnosis and a sufficient dose of antitoxin go a long way toward the prevention of operative interference. When the breathing becomes labored, steam inhalations may be tried. The croup-kettle is practically useless with children; in these cases a small close room, a large amount of steam and a quiet patient (morphine) are necessary to the successful employment of steam. Poultices sometimes work well, but often irritate the patient; in order that they may do any good whatever they must never be allowed to become cold. Emesis, I think, as a rule is too depressing and is seldom followed by the desired result, the expulsion of the membrane. In order that the membrane be expelled in this way, it must be loose and this naturally occurs toward the end of the attack, hence it is not practicable during the early stages. We come then to operative procedure, too often only resorted to as a last hope and for that very reason often failing to save patients in whom, had it been employed earlier, good results might have been obtained.

I shall not discuss the relative merits of the two operations, tracheotomy and intubation. Personally I prefer the latter, for there is only one condition in which the cutting operation is superior to intubation and that is when the membrane has extended lower than the intubation tube will reach, and often in these cases it has also extended beyond the reach of the tracheotomy tube.

We must be exceedingly careful and be sure that interference is absolutely necessary, for, despite the evident benefits to be derived from the procedure, it must be remembered that it also has its dangers. The presence of either tube is a source of irritation to the patient, the temperature almost always rises after its introduction, sometimes quite high, the nervous system being severely tried, and, above all, there is the ever-present danger of bronchopneumonia, but I can safely say that the frequency of this complication after intubation cannot compare with that of tracheotomy.

The color and pulse are the two best indications of the necessity for the use of the tubes. When other measures have been tried and have failed to give relief to the breathing and the pulse becomes rapid and weak, intubation should be performed immediately. If we find a patient resting apparently, but with a weak pulse, we judge that the efforts at breathing have been severe and prolonged and that the apparent rest is but exhaustion. A continued cyanosis without an indication of improvement calls for immediate relief.

In conclusion, let me say that especially in private practice it is better to insert a tube before it is actually needed than to postpone interference until the patient is beyond hope.

As a rule, a child can drink milk from a cup during the whole stay of the tube, but when this cannot be done resort may be had to the reclining posture, the head lower than the body, the child nursing from a bottle while in this position. On the whole, I think that when a patient cannot take nourishment in the ordinary way, and especially when there is regurgitation, we had better resort to gavage, the tube being passed preferably through the nose.

In post-diphtheritic paralysis, when this is general, systemic and general tonic treatment, including strychnine, which according to some exerts a specific influence, is about all that can be given. When the paralysis is limited to single muscles or groups of muscles, the faradic current is very beneficial.

ACUTE PELVIC SUPPURATION; ITS CONSERVATIVE TREATMENT.[1]

BY JOHN O. POLAK, M.D.,

OF NEW YORK;

ADJUNCT PROFESSOR OF OBSTETRICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; LECTURER ON GYNECOLOGY AND OBSTETRICS IN THE LONG ISLAND COLLEGE HOSPITAL, ETC.

In discussing this subject I will confine myself to a consideration of the causation and treatment of acute suppurative processes occurring within the tubes, pelvic peritoneum and cellular tissues about the pelvis, and will attempt to show that by the early recognition and timely evacuation of septic foci the sexual organs of the woman may be functionally preserved without exposing her to the risks of a major operation. The uterus forms the main avenue for infection and

[1] Read before the Kings County Medical Association, Oct., 1901.

there are certain periods which increase its susceptibility to attack by pathogenic organisms. These periods may be classed as post-abortal, post-partal, menstrual and post-menstrual. The lymphatics form another and even more available channel for the passage of pathogenic and pyogenic cocci. Lacerations and abrasions in the utero-vaginal tract permit their entrance and when once admitted their progress is rapid.

The gonococcus, staphylococcus, streptococcus, colon bacillus and tubercle bacillus are the principal organisms which invade the pelvis. It is doubtful if suppurative peritonitis is ever caused by either the colon bacillus or the tubercle bacillus acting alone, unless there has been a primary inflammation of either the colon or the appendix accompanied by extreme distention of the bowel or a mixed infection of a tuberculous focus.

The irreparable damage which continued pelvic suppuration can inflict upon the several pelvic organs of a woman is too well known to you all to need any word picture; and yet how few appreciate the simple and effectual means that we have for the arrest of these ravages. The normal Fallopian tube is germ-free, hence, if infection occurs in the oviduct, it must be by continuity from the uterus; purulent salpingitis may rapidly follow a gonorrheal endometritis. This is the most common form of pyosalpinx. The accompanying peritonitis is secondary, from leakage through the abdominal end of the tube; this further seals the fimbriated opening and a pus tumor develops.

The staphylococcus and streptococcus are the next most frequent producers of pus-tubes by the extension of a septic endometritis and are the chief causes of peritonitic and cellular infection. The lymphatics are their channel of election through which to reach the peritoneum. Tubal tumefaction is less common in this form of infection than when the gonococcus has been the invader. Though the tuberculous germ is credited with producing 10 per cent. of tubal inflammations, the pathological changes are seldom of an acute form, rather producing a hyperplasia of the mucous and submucous structures than the formation of pus accumulations.

It would seem, therefore, from the foregoing statements that all of these germs, with the exception of the tubercle bacillus and the colon bacillus, are capable of establishing an acute primary infection, passing rapidly along the uterus and tubes or through the pelvic lymphatics to the peritoneum. When primary the degree of peritonitis will correspond to the number of lymphatics which are involved. While the puerperal state exaggerates the virulency of streptococcic infection, the pregnant state after the third month seems to afford an immunity from the gonococcus. Also it must be noted that peritonitis of a gonorrheal origin is apt to occur at the menstrual period, and acute exacerbations in the course of a chronic gonococcic process are not uncommon at this time. In streptococcic infection the lymphatic invasion is so rapid that the formation of local foci will be found of rare occurrence; a general toxemia of more or less severity speedily supervenes. A general recognition of this fact will emphasize the necessity for prompt drainage.

The symptomatology and physical signs, together with an accurate history, will help to differentiate the local conditions. Clinically in pelvic suppuration the lines are not so sharply drawn as the books would lead us to suppose, owing to the rapidity with which neighboring structures are involved, making visceral isolation difficult. A history of abortion, labor, arrested menstruation, intra-uterine instrumentation or gonorrheal exposure, followed by pelvic or abdominal pain, fever, chilliness, anorexia, constipation or diarrhea and accompanied by a vaginal discharge of a purulent, sanguineous or a sanguino-purulent character, should call for prompt and careful pelvic exploration to determine the seat of attack. This examination should be abdominal, vagino-abdominal and recto-abdominal in the order named. Such a system adopted as routine will seldom fail to locate the septic focus. When, however, the infiltration is so extensive as to make visceral isolation impossible, vaginal incision and intra-pelvic exploration with the finger, when done aseptically and as a preliminary to subsequent operation, will obviate all possible error in diagnosis and guide the surgeon in his plan of procedure.

The pus focus may be found in the broad ligament, in the tube, in the ovary, in the pelvic peritoneum, safely walled off by exudate, or free in the peritoneal sac. The physical signs in the individual case will depend on the location and the character of the accumulation, *i.e.*, whether it be lymph, pus, or serum. The degree of general toxemia will also be largely governed by the nature of the infecting agent, thus widening the range of symptoms.

In acute salpingitis which has reached the form of a pyosalpinx, the uterus may be found more or less fixed on the affected side and displaced toward the opposite pelvic wall. A hard or fluctuating mass will be felt on vagino-abdominal palpation. This tumor may be in the cul-de-sac or high up near the pelvic brim. Whether the pus-tube can be isolated or not will depend upon the degree and the extent of the pelvic peritonitis in the particular case. The distended tube is usually closely matted to the posterior and lateral wall of the uterus. The disease is often bilateral; this is particularly true of infections of a gonococcic origin; again, it is not unusual to find a tubal abscess on one side and a purulent salpingitis on the other.

The differentiation between an acute ovarian abscess and a pus-tube is difficult. It is the writer's belief that such a diagnosis cannot be positively made until the cul-de-sac is opened; even then the two conditions so frequently co-exist and are so commonly involved in the same mass of exudate that isolation may be impossible. An

ovarian abscess is usually firmer and more rounded than a pus-tube, and commonly develops on one side only.

Tuberculous pyosalpinx cannot be diagnosticated macroscopically unless the tubercles can be seen or felt on the surface of the distended tube.

Streptococcic infection of the pelvic peritoneum is characterized by its rapidity, its marked general toxemia, and the almost constant absence of local findings. The pelvis is rapidly filled by fluid made up of straw-colored serum, pus-cells, blood-cells and lymph-flakes. Masses of lymph are uncommon. These points must be constantly borne in mind, as the tactile appreciation of free fluid in the cul-de-sac unless it be present in considerable quantity, presents difficulties which tax even the diagnostic acumen of the most skilled pelvic surgeon.

Masses of lymph surrounding and fixing the uterus, stiffening the broad ligaments, producing distention or stricture of the rectum and inhibiting the muscular action of the bladder, suggest staphylococcic or colon bacillic infection. Such lymph effusions resolve spontaneously, unless disorganized or infected by interference, and make up that class of non-operative cases referred to by Clarke in his excellent paper on the treatment of pelvic peritonitis.

Phlegmon occurring within the folds of the broad ligament invariably follows labor or abortion. The condition begins as a lymphangitis and cellulitis and ends in either resolution or suppuration. If it terminate in resolution, a thickened broad ligament is its only monument. On the other hand, if a phelgmon occur it may separate the folds of the broad ligament and bulge posteriorly lifting up and displacing the uterus laterally or forward toward the opposite pelvic wall. The diagnosis is comparatively easy when the condition is seen early or fluctuation may be elicited, while later the tumor may so fill the pelvis or become bilateral and so displace the pelvic contents that the seat of original infection may be lost sight of.

Fever, tympanites, pain, tenderness, an accellerated pulse-rate, and more or less toxemia are common to all of these infections. Of course the severity of these symptoms will differ in the individual case.

Treatment.—In order to establish a rational and scientific treatment in pelvic inflammation, two general classes must be appreciated, i.e., cellulitic and peritonitic lymph-effusions, and, second, pus accumulations in the tubes, broad ligaments, ovaries and pelvic peritoneum. In the first class, the general symptoms may be so mild that absolute rest in bed, light catharsis, rectal irrigation and the application of ice or poultice over the seat of pain will usually cause spontaneous resolution and gradual absorption of the exudate. It has been my fortune to open the abdomen for other conditions six months or a year after such an attack of pelvic inflammation, and to find little or no evidence of previous inflammatory trouble. I have been particularly impressed with the absence of visceral and parietal adhesions, showing that Nature undisturbed is often capable of fully re-establishing visceral mobility.

In the second class, which includes streptococcic infection without local foci, and mixed infections with pus accumulations, vaginal incision and drainage will afford the greatest protection against general intoxication. The French were wont to do this by panhysterectomy and drainage through the vaginal vault, but the writer has always claimed that the shock of a major operation in the presence of acute sepsis, no matter how rapidly or skilfully it may be done, more than counterbalances the advantage gained from the drainage secured.

Only a few years ago all pus-tubes were subjected to ablation by celiotomy. It was almost universally advocated that in the presence of a pus-tube on one side a double salpingectomy should be made. This practice had a reasonable basis, for, as we have already shown, tubal infection is commonly but an extension of an inflammation from within the uterus. Reasoning in this line the panhysterectomists said, if we are to take out both tubes, why leave an infected uterus to keep our patients from a complete cure? The advantage of vaginal drainage was also gained by this radicalism. Fortunately for woman the pendulum has swung from such mutilation toward scientific conservatism.

In acute pus collections, whether they be in the tube, ovary, or in the pelvic peritoneum, vaginal section and drainage will meet the indication and often conserve a set of pelvic organs which are capable of performing their functions with little or no pain. A further advantage is that the operation is rapid and produces little or no shock. I also claim that any intelligent practitioner who has perfected an aseptic technic may open the posterior cul-de-sac, separate fresh adhesions and drain pus cavities without being dependent upon the nearness of the gynecological surgeon.

By this procedure patients who are acutely septic are saved weeks of suffering and the prognosis is materially bettered. Later it may be necessary to have a more radical operation performed that a complete symptomatic cure may be attained, but in the vast majority of cases vaginal section and drainage when done early are truly life-saving and conservative in their results. Posterior section and drainage or some modification of that operation may be applied to almost every form of acute pelvic infection, including pyosalpinx, tubo-ovarian abscess, purulent peritonitis, parametritis, abscess and pus collections within the broad ligament.

A description of the method as applied to acute pus-tubes will serve as an illustration. The vulva and vagina are carefully sterilized and the uterus curetted; the posterior lip of the cervix is then siezed with a volsellum and pulled downward and forward, while a weighted speculum retracts the perineum and exposes the posterior utero-vaginal

junction; the mucous membrane of the vagina is incised transversely at this point (the incision is similar to the posterior incision for vaginal hysterectomy); the scissors are then replaced by the finger and the tissues peeled up from the back of the uterus; keeping in the median line until the peritoneum is exposed, the finger is pushed through the peritoneum into the pelvis and the opening enlarged by introducing the two index fingers into the cul-de-sac and spreading them apart. The perineal retractor is then withdrawn and the two fingers within the pelvis free all adhesions within reach, separating the tube and ovary of each side until they can be delivered into the vaginal wound for inspection. All who have done this work will acknowledge the facility with which adhesions are freed from below. With but little difficulty the adnexa can be brought successively into view, and, by the use of the Pryor position and trowel retractors, the whole pelvis may be inspected through the vaginal wound. If a pus-tube be present the following plan has been eminently satisfactory in my hands: After freeing the tumor from all adhesions, a sponge with a tape attached is passed into the pelvis; the distended tube is brought into the vagina and incised along its dorsum, beginning at the fimbriated end and running in for an inch or more; this empties the tumor of pus, which is washed away with saline irrigation. The tube is sponged dry and a fine probe carefully passed along its course into the uterus, thus determining its patency. The muscosa is sutured to the peritoneal coat with fine catgut. It may be necessary to repeat the procedure on the other side. I do the same operation in the presence of gonorrheal salpingitis, even when no tumefaction is present. Every adhesion must be freed before the final toilet is begun. The pelvis is sponged dry and a strip of iodoform gauze is tightly packed in each tube. The tubes are then replaced and the pelvis is loosely filled with strips of gauze or a Mikulicz bag with the adnexa lying above the drains. In this way the pelvis and uterus are isolated from the general peritoneal cavity and the lymphatics, the mouths of which were opened by separating the adhesions, pour out their fluids upon this mass of gauze. Thorough drainage is thus secured. I have found it to be an advantage to have the ends of the drainage gauze come out of the vagina and lie in a mass of dry sterile gauze. This should be frequently changed. The drainage gauze is withdrawn after five or six days. On the third day begin loosening it by pulling out a few inches. When once removed I have never found it necessary to replace it. *No irrigation of the pelvic cavity during operation or following the removal of the gauze is admissible.* The walled-off cavity will drain itself by gravity; this may be favored by urging the patient, when her condition permits, to assume the semi-recumbent posture.

In tubo-ovarian abscess incision and drainage are often palliative rather than curative; they arrest the sepsis, leave a functionating ovary which unfortunately may have too much cicatricial tissue in it, and produce such dysmenorrhea as to necessitate subsequent ablation. In the few cases that I have seen early, five in all, three have become pregnant since the operation, while the other two have had the adnexa removed for menstrual and intermenstrual pain. I have been impressed by several points which would justify the incision and drainage of every tubo-ovarian or ovarian abscess, *i.e.*, the subsequent operation has been much easier than in similar conditions which have not been previously emptied through the vagina; the patient was in better condition, the adhesions were more easily separated and the convalescence was smoother.

It is in pelvic peritonitis that vaginal incision and drainage have their widest field of application, for by these measures we are able to drain the lymphatics as they pour out their infecting organisms and isolate the pelvis from the general peritoneal sac. Even in purulent peritonitis early section in conjunction with the semi-recumbent posture may save our patient. When the toxemic symptoms have not improved twenty-four hours after curettage and irrigation my rule has been to open the cul-de-sac, free all adhesions, and drain with the patient's shoulders raised from eighteen to twenty inches. I have yet to see the case in which hysterectomy is justifiable when this simple procedure has been properly done.

In conclusion I wish to make the following statements and claims:

1. Early diagnosis in pelvic suppuration is imperative.
2. When the diagnosis is made, operate.
3. The vaginal operation is the one of choice.
4. When it is done early with strict asepsis it is curative and may preserve the function of the woman's organs.
5. It improves the patient's condition, makes subsequent operation easy, prevents rather than causes adhesions.
6. It may be used for diagnosis in obscure cases without shock or injury to the patient (if aseptically performed).

Finally, this operation may be applied to every acute suppurative condition within the pelvis.

VENTROFIXATION: A SUGGESTION.

BY VICTOR C. PEDERSEN, A.M., M.D.,
OF CORNING, N. Y.

One of the objections against ventrofixation as proposed by Professor Kelly is that the incision passes directly through the linea alba. Although the opening into the abdomen may be very small, it is, nevertheless, direct in its passage through this tendinous structure, which, like similar tissue everywhere in the body, is known to heal more or less unfavorably for strain, even when the union is primary. On the principle of Professor McBurney's intramuscular method of opening the abdomen for appendectomy, two ventrofixations were recently done by me in the

Corning Hospital on much the same plan. The principle is certainly not a new one and no claim to originality therein is made; but it seems desirable to describe the method and its results up to the present time merely as a suggestion. A similar procedure has probably not been described in medical literature, although the best journals on surgery and gynecology in French, German and English, and most of the really good works on these subjects have been searched for it.

The details are these: (1) Exposure of the sheath of the rectus through a median cutaneous incision two or three inches long; (2) strong retraction of the skin to one or the other side; (3) opening the sheath of the rectus about three-quarters of an inch from the median line; (4) liberal loosening of the rectus from its sheath and retraction of it as far outward as possible; (5) opening of the peritoneal cavity; (6) loosening of the peritoneum behind the linea alba; (7) search for large vessels at this point; (8) passage of the sutures as follows: The median edge of the peritoneal wound is seized with forceps and the needle is introduced half an inch away from the middle line; it is next carried through the uterus, emerging beyond the median line on the opposite side; it is then passed forward through the peritoneum, previously loosened as described, and then through the linea alba sufficiently deep to secure a firm hold; the two ends are then seized in an artery clamp; the other suture is passed in the same way and both are tied, so that the knot is extraperitoneal; (9) suture of the peritoneum; (10) restoration of the rectus to its sheath; (11) ordinary layer sutures close the rest of the wound.

The result of this operation is that the uterus is suspended in the median line, as in Kelly's original operation, while the scar is lateral to the point of fixation and is itself protected by the healthy rectus muscle, being "staggered."

In closing the sheath of the rectus mattress sutures were used, so arranged that they did not pull on a single bundle, but on many bundles of fibers. This was accomplished by passing the needle near the edge on the right side of the wound and emerging quite far from the edge on the left side. Then on the left side it again pierced the fascia near the edge and emerged on the right side far from the edge. When these stitches were tied this arrangement gave perfectly uniform apposition and the advantage of there not being any likelihood of their cutting through at the least strain.

Another detail which seemed very advantageous was the insertion of a retention catheter into the bladder before the uterus was suspended. With the aid of the catheter it is possible to inject into the bladder from six to ten ounces of sterile salt solution. In this manner the best place for fixing the uterus is clearly indicated, because, if the vagina is long and lax enough, the filling of the bladder can be increased and the uterus still suspended a little above it. By this process of measuring it is hoped that the bad after-effects of the operation, that is, pressure by the uterus upon the bladder for the first few months, as Kelly himself admits, will be avoided. It is perhaps suggestive that neither of my cases has suffered at all in this way up to the present time. The first woman was operated on for pronounced retroversion with adhesions, and the second for extreme pathological anteversion. Both suffered from obstipation and from frequent urination. The second patient had to empty her bladder night and day about every three hours. Since the operation she has been passing her urine about five times in twenty-four hours, which is a new experience for her after many years of great discomfort. It was felt that doing a ventrofixation for anteversion might be regarded as hardly warranted, but the symptoms were such as to make me believe that only a lifting of the uterus away from both bladder and rectum would avail. As the woman desired to have children, if possible, no other operation could be contemplated except ventrofixation. The results up to the present time have proved this judgment to have been entirely correct.

A CASE OF LEUCEMIA, PRECEDED BY MUCO-SANGUINOLENT COLITIS AND PHYSIOLOGICAL LEUCOCYTOSIS.[1]

BY G. W. M'CASKEY, A.M., M.D.,
OF FORT WAYNE, IND.;
PROFESSOR OF CLINICAL MEDICINE AND NERVOUS DISEASES, FORT WAYNE COLLEGE OF MEDICINE.

The whole question of the etiological rôle of toxemiæ of intestinal origin is involved and obscure, although its importance cannot, in my opinion, be doubted. In dilating so largely upon this subject, in the report of a single case, it is largely for the purpose of indicating what appears to me to be its broad relations to clinical medicine in general, and especially to chronic intestinal diseases. So far as the etiology of leucemia in general is concerned, and of this case in particular, the sequence of carefully observed facts is presented as a contribution to a very difficult, and still unsolved problem, which will require for its ultimate solution, if indeed it is ever to be solved at all, a more extended view-point than is at present accessible. The following is the report of the case:

L. D., age twenty-three years, school teacher. The patient had never been of rugged appearance, indeed, quite the contrary, although capable of enduring a great deal. There was a history of post-scarlatinal dropsy at three years of age, and several attacks of "bloody flux" at ten. History otherwise not noteworthy. The patient was first seen by me in winter of 1897 at which time he was suffering from a moderately severe grade of secondary anemia, apparently the result of overwork and an intense chronic colitis of one or two years' duration, accompanied by frequent dis-

[1] Read before the Kankakee Valley Medical Association, Plymouth, Ind., October, 1901.

charge of mucus and blood. These symptoms had existed for several months. At that time the red cells were 3,500,000, hemoglobin 65 per cent., with a leucocytosis of about 14,000. Stained slides showed the leucocytosis to be strictly physiological in type, the differential count revealing the proper proportion of neutrophiles, and large and small lymphocytes, no mention being made of the number of eosinophiles; but it is certain that no abnormal forms of leucocytes were present, such as the myelocytes which appeared in such large numbers later. I saw the patient, who lived some twenty miles from my office, only a few times when he disappeared from view.

He again reappeared March 30, 1899, with a history of progressive deterioration of health, the symptoms being much the same in character as when first seen. For some months the diarrhea had been persistent, and controlled with difficulty, but was the greater part of the time of a thin, watery character, and at that time rarely contained blood. He had to take opiates constantly in order to control the diarrhea so that he could sleep. The spleen was remarkably enlarged, extending down within about two inches of the pubis, and to within two or three inches of the right anterior superior iliac spine. Its consistence was firm and its extensive outline irregular and notched. The liver was also greatly enlarged. Stomach examination showed entire absence of free hydrochloric acid, with perfect starch digestion, but very faint biuret reaction. There was no lactic acid, and the total acidity was very low—10°. The fasting stomach contained the usual detritus of chronic gastritis, the quantity of mucus in both the fasting stomach and gastric juice being large. Microscopical examination of the dejecta revealed a morbidly intense bacterial growth, with many protozoa, and large quantities of epithelial cells and mucus. The filtered aqueous infusion of alvine discharges was shown by the spectroscope to contain unaltered bile, which with bile stained microscopical flocculi of mucus established the diagnosis of a catarrhal lesion of small as well as large intestine. The acrid alvine discharges, together with the local infection, had developed and maintained a severe proctitis which was a source of great suffering.

The analysis of urine gave the following result: Total quantity in twenty-four hours, 1,600 c.c. (about 1½ qts.); specific gravity, 1,020; total solids, 74.56 grams; urea, 3 per cent. or 48 grams; uric acid, 1.8 grams; no albumin, sugar, indican, phenol, nor diacetic acid.

Notwithstanding the absence of an excess of both indican and phenol the ethereal sulphates, estimated by the method which I published in the *Journal of the American Medical Association*,[1] were greatly increased. The simple or fixed sulphates were 2.3, the ethereal sulphates .9, estimated as SO_3. This was in proportion of 2.8 to 10 instead of 1 to 10 as in health.

[1] Jour. Amer. Med. Assoc., March 31, 1900

The blood examination furnished the key to the case. The blood was found to be of a peculiar, opalescent hue and exceedingly thin. There was scarcely any pretense at coagulation, the drop remaining fluid on the finger until it thickened by evaporation, with the ultimate formation of a loose coagulum.

The hematocrit showed about 40 per cent. red cells, indicating about 4,000,000 per c.mm.; this however was found to be somewhat in excess of the figures obtained by the Thoma-Zeiss apparatus. The discrepancy did not lie in the size of the red cells, which were of about average size, but, as shown by a microscopical examination of the red column, was due to a large admixture of white cells, which does not occur in centrifugated normal blood. It appears to me that there is only one probable explanation of this phenomenon, and that is the greater specific gravity of the leucocytes in leucemic blood and especially of the myelocytes. This is an observation of some scientific interest which I do not remember seeing recorded before. The rouleaux formation varied greatly. It was sometimes normal and at others very feeble. The hemoglobin was reduced to about 50 per cent. of the normal, showing a greatly diminished color-index. The chief interest, of course, centered in the study of the dried and stained slide. It was typical of splenic medullary leucemia. The red cells presented nothing especially noteworthy, excepting pallor, an occasional normoblast, and the polychromatophilic degeneration of Ehrlich. With regard to the white cells, however, the properly stained slide showed a large number of myelocytes—that form of cell which is highly characteristic but not pathognomonic of lieno-medullary leucemia. This cell resembles the neutrophile in having the neutrophile granules, and the lymphocyte in presenting a spherical, ovoid, or some other form of nucleus, without divisions, and very large in proportion to the containing cell. The nucleus stains with variable intensity, and the granules may be eosinophilic instead of neutrophile. The myelocytes vary greatly in size, some of them being very large. The largest one that I found among many measurements in this case was about 20 μ

While, as I stated, the mere presence of myelocytes is not pathognomonic of leucemia, their presence in large numbers is absolutely so. If they form 10 or 15 per cent. of the total number of leucocytes, the diagnosis of leucemia may be positively made from this fact alone. The percentage is generally much larger than this. In this case, for instance, one of many differential counts gave the following result in a count of 515 leucocytes: Polymorphonuclear neutrophiles, 180 or 35 per cent.; simple myelocytes, 162 or 31 per cent.; eosinophile myelocytes, including all those in which there was a distinct tendency toward the acidophile staining of granules, 51 or 10 per cent.; total myelocytes, 213 or 41 per cent.; large lymphocytes, 43 or 8 per cent.; small lymphocytes, 65 or 12 per cent.; ordinary eosinophiles, 2 or .2 per cent. At this particular time

the white-cell count was 277,200 per c.mm. Estimating the number of different kinds of white cells per c.mm. present at this time, we have, in round numbers: Polymorphonuclear neutrophiles, 97,000; simple myelocytes, 85,900; eosinophilic myelocytes, 27,700; total myelocytes, 113,600; large lymphocytes, 20,000; small lymphocytes, 33,000.

The patient's general condition was very bad. He looked pale and anxious, and was emaciated to a considerable degree. He was under my observation, either directly, or as a consultant, for a year and a quarter up to the time of his death. It would not be justifiable to present the detailed history of the case during this time, with a full discussion of the treatment. Arsenic, the various preparations of iron, bone-marrow and thyroid extract were among the remedies exploited in the case. While there were periods of improvement, the general tendency was downward, the latter tendency being often accentuated by indiscretions on the part of the patient, whose endurance, as usual in such cases, was severely tested. The most important measures of treatment were those directed toward the gastro-intestinal disease, which certainly preceded, by a considerable time the hemic changes of leucemia. The gastritis was treated by local measures, lavage, intragastric faradization, etc., with marked improvement of the digestive function. This I consider a proper procedure in any case of chronic nutritional disease, without any regard to the real pathology of the case in its relation to the gastric disease.

The determining question from a therapeutic point of view, in my opinion, is, Have we to deal with a stomach lesion which is, under the circumstances, amenable to such treatment, with a probability of improving the condition of the patient to a noteworthy degree? In such a case as this the only hope of greatly prolonging life is to improve the general nutrition, and the primary digestion is fundamental in this regard. In this case the improvement in digestion was followed at times by so marked an improvement in the general condition, as to lead to the hope of a long stationary period. I feel confident that such a result might have been attained, but for the unfortunate intestinal lesion, which has very much the appearance of being the principal etiological factor in the case, but in any event was so severe as to baffle all attempts at its removal. This was due, doubtless, quite as much to the bad state of general condition as to lead to the hope of a long lesion itself. It was this apparently, more than anything else, with its incessant pain and exhaustion which dragged him down to death.

The nature of this lesion has already been indicated. Its treatment cannot be described in detail. As already stated, opium in varying dosage had to be called into almost constant requisition. It was used, however, to the least extent compatible with the reasonable relief of the severe symptoms, and was constantly supported, and sometimes supplanted by other measures. Locally the colitis was treated by silver salts, including protargol, boric acid, and various other antiseptics. Suppositories of lead, opium, belladonna, etc., were frequently resorted to. Internally eosot and subgallate of bismuth were principally relied upon.

Only a small contingent of the remedial agents and measures utilized in the case can or need be referred to here. As already stated the general tendency was downward, and death from asthenia resulted June 10, 1900, fifteen months after the diagnosis of leucemia had been made.

The autopsy included a careful examination of the abdominal and thoracic viscera only, the bone-marrow not being examined. The spleen was greatly enlarged, weighing three and one-half pounds, and very fragile in consistence. The liver weighed about five pounds, and was distinctly indurated. The colon showed evidences of the intense inflammatory action of which it had been the seat. There were numerous deep abrasions, some of which could be properly classified as superficial ulcerative processes. The small intestine was normal macroscopically. The only noteworthy thing about the heart was the presence of the soft white coagula described by Virchow and which were found to be composed principally of leucocytes.

There are several points in this case which appear worthy of record and discussion. The most important one, I think, is the existence of chronic colitis of long standing, associated perhaps the greater part of the time with a catarrhal condition of the small intestine; this, taken in connection with the physiological leucocytosis definitely recognized before the appearance of myelocytes, raises a very interesting question of etiology. The belief that intestinal disease may bear a causative relationship to leucemia is not new, although perhaps it has rarely happened that the order of events has been so definitely established as in this case. Saunby has recently reported in the *British Medical Journal* a case with ulcers. How soon after my first observation of this case myelocytes appeared in the blood, and especially in sufficient numbers to establish the diagnosis of leucemia, is, unfortunately, a matter of conjecture only, as no scientific study of the blood was made in the interval.

The sequence of chronic colitis and leucemia being established in this case, the relationship of the latter to the former—whether a result or an independent development—is a question of deep interest. Owing to the very unsatisfactory state of our knowledge of the pathology of leucemia, it is difficult, if not impossible, to discuss clearly this question along definite lines. There are, however, certain considerations of a general character which appear to me well worthy of attention.

The state of general and local nutrition, incident to such a case of chronic colitis as the one reported, must obviously be very bad. The colon is of course the seat of a chronic infection which is associated, necessarily, with the formation of relatively large quantities of toxic substances of

various kinds, the precise nature of which we cannot determine. Owing to the lowered antitoxic coefficient of the liver, the absorption of these products into the portal circulation is followed by their entrance into the systemic circulation to a great extent unchanged in form. The liver is, owing to its physiologico-anatomical relationship, the first structure to suffer from the absorption of toxic material from the alimentary canal, and, just in proportion as its functional integrity is impaired, do the structures which it is designed to protect suffer in consequence.

It is not necessary to regard leucemia as a pure infection in order to perceive the possible causative relationship of an intestinal infection. The sharp distinction between lymphatic and myelogenous leucemia can scarcely be maintained in the light of recently reported facts. Cases with a preponderance of large mononuclear cells have been observed with extensive involvement of lymphatic structure, while Widal and Muklen have recently reported a case in which the picture was that of a pure lymphatic leucemia, while the bone-marrow was found at autopsy to be composed of a tissue containing nothing but lymphocytes. Admitting that leucemia is a primary disease of the bone-marrow, the operation of an exciting cause can still be rationally assumed, and sought for. This is precisely the rôle that I would assign in the existing state of our knowledge to such conditions as anteceded the development of the leucemia in the case here reported. From this point of view something more than the toxemia and malnutrition of intestinal origin is necessary for the production of the leucemia. Just what that "something" is cannot be readily defined. It may be spoken of as a special vulnerability—a peculiar tendency to take on degenerative changes of the embryonic type—on the part of the tissue under consideration. If this explanation is unsatisfactory it is no more so than the explanation given of the frequently observed fact of large families being swept away at about a certain age with pulmonary tuberculosis. The practical fact is, dress it in whatever terms one chooses, that there are morbific tendencies in certain families and individuals, which render destructive agents operative in the production of certain results. Yet these tendencies, without the exciting causes, would scarcely, if ever, give rise to any particular disease, and, of course, in the case of specific infections like tuberculosis, could not do so under any circumstances, although it is quite conceivable that such results might follow in diseases like leucemia, in which the principal factor may possible be the degenerative tendency to which reference has been made.

While the clinical picture of leucemia impresses me as it has many others, as having many of the features of a general infection, yet I do not for a moment believe there is available evidence for assuming the existence of a specific infection in the ordinary sense of the term; nor is it necessary to do this in order to assign an important rôle to the general infections of varied and indefinite character which arise from the various mucous surfaces of the body and especially from the gastro-intestinal tract. From this point of view the results of a general infection of the character referred to will depend very largely upon what may be termed the personal equation of the individual, and to go a step further, the resistive power and functional integrity of the organs and structures of the individual. This is, perhaps, equally true of the specific infections, the only difference being that their effects are not so variable—it is usually either a definite clinical picture or it is nothing.

107 W. Main Street.

MEDICAL PROGRESS.

EYE, EAR, NOSE, AND THROAT.

The Epipharyngeal Tonsil.—In an article on the nature and histopathology of this structure, N. H. Pierce (Jour. Amer. Med. Assoc., Jan. 4, 1902) submits the following conclusions: (1) The tissue composing adenoids has a wide distribution throughout the body, especially abundant in the pharynx and in the ileocecal region of the intestinal canal, also in the conjunctiva, tear-ducts, genital mucosa, larynx. (2) The epipharyngeal tonsil is normally present in all individuals. (3) Its function is at present unknown. Whether it is simply an evolutionary vestige or has to do with metabolic processes is uncertain. (4) It probably belongs to the class of glands having an internal secretion. (5) The relation of tuberculosis, syphilis, or scrofulosis to adenoids is not etiological.

Ulcer of the Cornea.—Progressive ulcers anywhere on the eye are dangerous and at no point are they more threatening than on the cornea. A. M. Ramsey (Med. Press & Circ., Dec. 18, 1901) recommends the following treatment for traumatic serpiginous ulcer of the cornea: Rest by keeping the patient in a dark room, protection from further injury, and the relief of pain are the first three indications. The patient should be kept in bed in a dark room with the eyelids closed by a bandage. In order that the bandage may be laid smoothly and not exert an uneven pressure a carefully-fitted pad of cotton which fills up the hollows of the eye should first be applied. A poorly-fitting bandage is worse than useless. Discharge from the lacrymal sac must be arrested and the tear-passages kept cleansed. Atropine is the best drug for the iritis which always complicates this form of ulcer. It soothes the nerves, diminishes congestion, dilates the pupil, paralyzes the ciliary muscle and insures rest for the eye. Its effect upon the pupil is a guide to prognosis; the more quickly the iris responds, the more favorable will be the course of the disease. Leeches over the temple decrease congestion and pain. Free bleeding always does good. When the ulcer is about to perforate, eserine should be substituted for the atropine. This drug has a more limited use. In this condition and almost invariably the atropine should be preferred in a solution of one to two per cent. until the very last stages. Moist heat may be applied to the temples and face to relieve congestion and reduce intra-ocular tension. Further progress of the ulcer demands disinfection of its surface. Nothing is better than the application of hot saturated solution of boric acid continued until all discharge has been washed away; then a powder of equal parts of iodoform and boric acid very finely triturated should be dusted freely on its surface. Other disinfectants are a collyrium of chino-

sol, one part in four thousand, and protargol, five parts in one hundred. The injection of mercurial salts beneath the conjunctiva is to be deprecated. Constitutional treatment is always necessary and is carried out by good food, alcoholic stimulants, quinine in full doses, and morphine according to indications. If the ulcer be still progressive, surgical measures may become necessary. A bold incision of the cornea through the ulcer into sound tissue is recommended on the authority of Saemisch of Bonn; this is, in short, the same treatment as for an abscess elsewhere. The hypopyon is evacuated by this method and then drained by keeping the wound open. Care must be taken to avoid a prolapse of the iris, which almost certainly follows in many cases. Another operation available is to destroy the edge of the ulcer. For this purpose an alkaline solution of fluoroscin is dropped into the eye, which makes the margin of the ulcer a bright green. A fine platinum cautery at dull red heat is then applied to the cornea in healthy tissue just beyond this green line. The burning is continued until all of the infiltrated margin is destroyed. The healing of the ulcer will be promoted by the reduction of intra-ocular tension. The cornea should be incised at its outer aspect and the anterior chamber of the eye slowly emptied. Congestion and hemorrhage within and displacement and partial prolapse of the iris accompanied by great pain often follow this procedure. Hot poultices will usually control these symptoms. If the destruction of the ulcer with the cautery be well done, the healing process is rapid and the scar is comparatively slight, considering the dreadful type of the ulcer.

Haab's Magnet for the Extraction of Foreign Bodies from the Eye.—From a study of nine cases in which this instrument has given favorable results, W. T. H. Spicer and A. F. Maccallan (Brit. Med. Jour., Jan. 18, 1902) reach the following conclusions: (1) When the patient is brought up to the magnet, it is the rule for severe pain to be experienced by him if a magnetizable particle is present in the globe. Haab's magnet is therefore of valuable diagnostic service in determining the presence or absence of such a particle. (2) Localization by the X-rays is extremely important. By their means it is possible sometimes to avoid injury to a clear lens in the extraction of a foreign body and entanglement of the iris can be avoided if its precise situation be known. (3) If there be a recent wound we attempt to remove the foreign body through it, using Haab's magnet alone. If this wound has firmly healed, it is necessary to make an opening for its exit. This may be either corneal, in which case the foreign body is withdrawn by Haab's magnet, or peripheral, in which case the small magnet for the removal of the foreign body from the anterior chamber, after it has been brought forward by Haab's magnet, is usually employed. (4) In all cases it is most essential that entanglement of the particle in the iris and ciliary body should be avoided. By gradually bringing the patient from a distance up to the magnet and by increasing slowly the strength of the current up to the maximum, this is to a certain extent guarded against. The idea is to prevent the particle from rushing forward from its posterior position and burying itself in the iris.

Sympathicectomy in Optic Atrophy.—Many cases of simple glaucoma have been so markedly benefited by the excision of the sympathetic ganglia that this operation has been suggested for the relief of other conditions when vascular changes were necessary: The reduction of tension which follows sympathicectomy in eyes with normal as well as in those with increased tension, lessens the pressure on the intra-ocular portion of the optic nerve. Then the vaso-dilating effect of section of the sympathetic nerve increases the blood-supply of the nerve, both of the intra-ocular portion and the orbital. This healthful artificial arterial hyperemia promotes a regeneration of the nerve elements and a resulting restoration toward the normal state, with a conseqent increase of its function, vision. Nitrogylcerin has been found to do the same thing, but its effects are more temporary. E. C. Renaud (St. Louis Med. Rev., Feb. 1, 1902) has operated on these cases of simple nerve atrophy, founding his indications upon the above well-known principles. In the first case a unilateral operation was done and the improvement in vision was only slight. In the last two excision was done on both sides and the results were much better. In glaucoma also operations seem to be necessary on both sides in order that the best results may be obtained, probably on account of the intimate relations of the sympathetic systems at the base of the skull. In the third case vision has improved from 10-200 to 20-50 and this seems to have been permanent. He believes that the incision behind the sternomastoid muscle is preferable to the one in front of it on account of the ease with which the internal carotid artery and jugular vein are gotten out of the way. Furthermore the field of operation is larger. He recommends tearing the ganglion out rather than cutting it, for by the latter method parts of the ganglion must be left and may continue to exert their influence.

Rhinopharyngeal Origin of Goiter.—In no case of goiter has Dr. Hamon du Fougeray of Mans (Rev. Hebdom de Laryn., Rhin. et Otol., No. 1, 1902, p. 20) found rhinopharyngitis absent. Treatment of the latter has improved all of his 209 cases and cured many. Exophthalmic goiter has also been helped. His theory is that congestion of the thyroid gland is produced by reflux of blood from the pharyngeal into the thyroid veins. He sums up as follows: (1) Vascular lesions of the oropharynx cause simple goiter of the cavum and of the nose, exophthalmos; of both nose and pharynx, exophthalmic goiter. (2) Mixed lesions, vascular and sympathetic of the oropharynx, cause goiter and heart troubles—of the vault of the nose, exophthalmos and heart troubles; of the whole rhinopharynx, typical Basedow's disease. (3) Sympathetic lesions alone, of oropharynx, of the cavum and nose, of the whole rhinopharynx, cause cardiac troubles without goiter or exophthalmos.

OBSTETRICS AND GYNECOLOGY.

Spinal Anesthesia in Obstetrics.—This procedure has been used in obstetrics for two distinct purposes, says A. W. W. Lea (Jour. of Obst. and Gyn. of the Brit. Empire, Jan., 1902), (1) to mitigate or remove the pain of labor, and (2) as a method of analgesia for performing obstetric operations. The duration of analgesia is insufficient to render labor free from pain unless repeated injections are given. This plan exposes the patient to the risk of toxic symptoms, and also to the dangers of repeated punctures of the subarachnoid space, and hence cannot be generally advisable. It is, however, possible to give injections when the os is almost fully dilated, and so produce analgesia throughout the second stage of labor; but under these conditions small doses of chloroform give very good results. It has been held by some, Lucas, Championnière, Schroeder, Boudin, that chloroform tends to produce hemorrhage not more frequently than in normal cases. If, however, a distinct tendency to hemorrhage is present, spinal anesthesia by cocaine may by its stimulating action on the uterine muscle possess certain advantages. Up to the present time it has been adopted in over two hundred cases without any serious accident. Puech

considers that up to the present time its superiority over chloroform has not been demonstrated in that it does not produce painless labor nor in operative work have its advantages over chloroform been established.

Contraction and Retraction of Uterine Muscle.—In the first number of the Journal of Obstetrics and Gynæcology of the British Empire PETER HORROCKS says that the following points may be stated: (1) Contraction of a muscle is generally, but not always, accompanied by an approximation of its two ends. (2) When a muscle is shortened to its fullest extent, it can relax or contract without becoming longer or shorter. (3) When muscle contracts, it is unable of itself to return to its former condition: some other muscle or force is required to pull it out or extend it. (4) When muscle contracts and then simply relaxes, it is in a condition called retraction. (5) Retraction is a condition of a muscle in which the active contraction has given place to simple relaxation without extension. (6) In a state of retraction there is a slight and constant contraction called tone. (7) Retraction may be partial or complete, according to the amount of preceding contraction. If the muscle has contracted to its fullest extent before relaxing, the retraction is complete; if anything less than its fullest extent, it is only partial. (8) Retraction of the uterus in labor affects only the expulsive fibers of the fundus and upper two-thirds of the body of the uterus. It keeps the sinuses and broken blood-vessels of the placental site closed, and is therefore of the greatest importance. (9) After the third stage of labor the uterus is sometimes in an active state of contraction, when it is more or less spherical and feels hard and well defined in outline, and sometimes in a state of relaxation, when it is softer and less spherical, and not so defined in outline; but such a condition is quite normal, and in no way indicative of danger. (10) Labor pains are in all probability reflex acts. (11) The less they are interfered with the better. (12) Complete retraction of the uterus is the safest condition for the prevention of postpartum hemorrhage. (13) Complete retraction is obtained by complete contraction followed by relaxation. (14) The law of polarity, as applied to the uterus, is that when the expulsive fibers contract the sphincter fibers relax, and permit themselves to be stretched or extended. (15) The cervical canal can be opened up apart from pressure within, and this is accomplished probably by relaxation of this circular fiber and contraction of the longitudinal fibers of the cervix and lower zone of the body of the uterus. (16) Painless uterine contractions taking place during pregnancy are not followed by retraction, because the fibers are stretched out again by the hydrostatic pressure of the liquor amnii.

Polypi of the Meatus Urinæ.—These are usually situated on the floor of the urethra about two or three millimeters from the orifice of the meatus. They are derived from the epithelioma, from the blood-vessels, from the glands or are from papules of the urethral mucous membrane. Again all portions of the mucous membrane may take part in their formation. They may be single or numerous. They occur at all ages, but most frequently between twenty and thirty. The commonest causes of them are blennorrhagia, leucorrhea, irritation from menses, and coitus. The symptoms are dribbling of urine, sensation of a foreign body in the urethral canal, frequency of micturition, burning and pain during micturition and coitus, bloody discharge, pains in the lower portion of the abdomen and in the groins. The diagnosis can usually be readily made, but when one suspects malignant growth a small portion can be removed and submitted to microscopical examination. The prognosis is good, but there may be complications, such as cystitis, urethritis, uretrocele and prolapse of the urethral mucous membrane. Rarely they may become epitheliomata. Various treatments have been employed in their removal, all of which must be operative to procure an ultimate cure. Some tie off the pedicle, others snip them off with knife or scissors and cauterize the base. The most effective method, however, is to proceed after the same method as is employed in the Whitehead operation for the cure of hemorrhoids. The mucous membrane is separated just as is the pile-bearing area and that portion containing the polypi is drawn down and cut away. The cut portion of the mucous membrane is then brought down and sutured to the orifice of the urethra where it was previously incised. Interrupted sutures are to be used. Four or five are usually sufficient to get a good approximation, according to LEROY (Gazette de Gynecologie, Jan. 1, 1902).

Operations for Retrodisplacements and Prolapse.—The final results of any method of treating disease is always instructive. On account of the rapid progress that surgery has made in the last twenty-five years, statistics concerning it are especially interesting. H. ANDERSCH (Arch. f. Gyn., B. 65, H. 2) reviews the various methods of treating retroflexion and prolapse of the uterus by operation. With special reference to the results obtained, his conclusions are the following: (1) All non-adherent retroflexions with or without prolapse or descent should be treated with pessaries whenever possible. (2) Non-adherent retroflexions, which are complicated with prolapse or descensus of even a very small degree, and all cases of prolapse or descensus without retroflexion of the uterus should be treated by vaginal fixation, if pessaries cannot be worn, and in accordance with the age of the patient. (3) The rare forms of isolated retroflexion of the uterus, with mobility, which cannot be treated with pessaries, must be subjected to either a ventral fixation or an Alexander-Adam operation. (4) All adherent retroflexions of the uterus which require operation at all should be treated by ventral fixation.

Vesico-Vaginal Fistulæ.—Any new rational method of treating these obstinate and troublesome lesions should be hailed with delight. M. A. CASAMYOR (La Gynec., Dec. 15, 1901) presents the following technic for small fistulæ, which certainly pleads a great deal in its favor: The patient is placed in Sims' position and four artery clamps are applied about the margin of the fistulæ after the latter have been cleaned of granulations and fragments. The four clamps are then seized as retractors and the anterior wall of the vagina is drawn toward the vulva into a funnel shape. While so held the wall of the bladder is stripped off the vaginal tissue and turned inward toward the cavity of the bladder. This dissection is carried out all around the fistulous opening and upward for one and one-half to two centimeters. When this step has been accomplished a purse-string suture is passed through the vaginal tissue, which is on the vaginal side of the points where the two layers are in normal anatomical relation. While traction outward is made the purse-string suture is tied and reënforced by one or two interrupted sutures across the opening in the stump which then occurs. A retention catheter is then introduced and retained for four or five days. His cases have done exceedingly well under this simple maneuver.

Triplets.—Multiple births among mankind are after all not by any means uncommon, and any contribution which seeks to explain their cause is of scientific interest. Such is presented by R. SAINTER (Z'schr. f. Gbtshülfe. u. Gyn., B. 46, H. 3). He gives the following data: Out of 70,477 births, 30 cases of triplets alone have been noticed. This is too large a number

but is due to the fact that at the institution in which the statistics were gathered a very large number of the women are primiparæ. This would make the average one set of triplets in every 2,349 births, which is certainly not the truth. Another reason perhaps for the large number is that in multiple births a physician is often on hand and the case is suitably recorded. The revised and modern statistics from all possible sources make their occurrence practically one in eight thousand births. Quadruple births seem to occur once in 371,126 cases and twins once in 89. The age of the mother is a factor in these cases. In twins the greatest number give birth to them between the twenty-fifth and thirty-fourth years, while in triplets the range is from the thirtieth to the thirty-ninth year. The number of previous pregnancies in the same mother always appears to have an influence. There is no doubt that multiparæ show the greatest tendencies toward triplets, and the greater number of children a woman has had the greater is her chance of having either twins or triplets. The revised and modern statistics show further that as a rule triplets occur among the youngest children of very large families on the average oftener than do twins. The character of the previous pregnancies is also a factor in the case. The individual disposition of some women to twin pregnancies is already accepted and indeed to multiple births also. Meribeau has found cases, seventeen in number, in which three, four, five or even more children were born at the same time. Sainter himself has seen three mothers of triplets who had previously had twins once, one mother who had twins once and triplets once previously, and another who had had twins twice and triplets once previously. There are other conditions connected with the pregnancies which are along the line of abnormalities. Many women who have triplets give a history of many miscarriages and abortions. The author has seen eight cases with one abortion, two with one miscarriage at seven months, others with two, four and three abortions respectively, and the last added two miscarriages in addition. Heredity is another matter to be remembered. It holds as well for triplets as for twins. He has seen one case in which the mother herself was a twin; in another brothers and sisters were twins, and in the third the mother had had twelve single and two twin children. The duration and course of the pregnancies are also important. The rule seems to be that the majority of threefold conceptions are not carried to term, but are ended in the second half of the eighth month. A great many of these patients are lost before the pregnancy is half over. The nature of the delivery itself is important to remember. The average length is twelve hours, as in single or double births. The interval between the appearance of the children may be very short or very long. The average is about half an hour, but such intervals as four, six, nine and a quarter, and twelve and one-half hours have been noticed. There is at the present time, however, no record in which the delay between the births of the children has been a matter of days or even weeks, as is sometimes seen with twins, making such pass into the category of superfetation. Childbed is as a rule normal and favorable. The prognosis for threefold conception is as good as for single conception with the sole exception that eclampsia is the chief danger. The children are necessarily much smaller than in twins or in single births. The records show that in 768 cases all were boys 409 times, and all were girls 359 times. Where the sex was mixed in a total of 921 cases two boys and one girl occurred 504 times and two girls and one boy 420 times. The formation of the placenta is the latest point of interest. It seems as if the rule were that the after-birth is divided into two sections most frequently. Next it occurs as one large mass and least frequently there are three separate after-births. Triplets produced from one ovum, as is shown by the occurrence of one chorion, have been recorded only twice. The children therefore had one placenta and were all of one sex. Triplets produced by two ova have been recorded fourteen times. Such would have usually two, never three, placentæ. Triplets produced by three ova, in which each had its own chorion, have been found but nine times. In this case, of course, the children had each its own placenta, but six of the cases had two placentæ. The essential cause of such threefold conceptions is not known and probably never will be.

PATHOLOGY AND BACTERIOLOGY.

The Blood in Syphilis, Tabes and General Paralysis.—In primary syphilis examination of the blood shows a moderate anemia, a positive leucocytosis, and a relative increase in lymphocytes. In the secondary period, according to Sabrazes and L. Mathis (La Presse Méd., Jan. 22, 1900) the anemia persists; polynuclear neutrophiles are now increased in number; the percentage of eosinophiles is low. Mercurial treatment causes an elevation in the number of red and of white corpuscles. In tertiary syphilis the blood approaches normal. In tabetics a slight decrease in corpuscular elements was observed, with some degree of relative hyperleucocytosis. In general paralysis, the stage of euphoria is characterized by eosinophilia and a high red blood count. In none of the cases just referred to was there any morphological alteration other than polychromatophilia, and even this was rare.

Compensatory Hypertrophy of the Kidney.—In order to ascertain the pathological changes present in compensatory hypertrophy of the kidney, Gino Galeotti and Gius. Villa-Santa (Beiträge zur path. Anat. und allg. Path., B. 31, H. 1) have observed the results of unilateral nephrectomy upon dogs and rabbits. They show that the changes in the hypertrophied kidney vary accordingly as the animal is young and in the development stage or is full grown. In the first instance the number of the glomeruli is increased; in the second there is no increase in number, but each is markedly increased in size. The result is the same in both cases—an increased functional activity. The work is of interest in showing how cells under different conditions of life react to a stimulus which calls for an increase of living substance.

Iodophilia.—Iodophilia, so-called, is the reaction which certain of the white cells of the blood show when a dried blood film is brought in contact with a drop of the following solution: Iodine, 1 gm.; potassium iodide, 3 gm.; water, 100 c.c.; gum Arabic, 50 gm. Normally under these conditions the leucocytes stain a bright yellow, the nucleus being somewhat more refractile than the protoplasm, so that the different varieties of leucocytes can be easily differentiated. In certain pathological conditions the uniform coloration is broken by the appearance in the protoplasm of the polymorphonuclear neutrophiles of reddish-brown granules, or a diffuse brownish coloration, and by the presence of small and large masses, outside the corpuscles, similarly colored. There is thus present an extra- and an intracellular reaction. E. A. Locke and R. C. Cabot (Jour. Med. Research, Jan., 1902), as the result of extended observations in regard to the occurrence of this reaction, believe that the brown masses outside the corpuscles are present in small numbers in all blood both normal and abnormal, but frequently in such minute amounts as to be found only after long searching. Only an increase of these masses is to be

considered pathological. They are uniformly and markedly increased in diabetes mellitus, in chronic and very severe acute suppurative diseases and rarely in a few other conditions, but in general their increase is of little importance from a diagnostic standpoint. The intra-cellular granules are always to be considered as pathological. Their presence does not signify a special disease or condition but a general toxemia. Though more constantly positive in the presence of pus than with other conditions, one cannot make a diagnosis of sepsis or of a purulent accumulation from their presence alone. Iodophilia is not identical with, neither does it coincide in its indications with, any of the ordinary physical signs, as leucocytosis, fever, etc. The authors have never observed this reaction in any but severe cases and they believe it to be more reliable in this respect than either leucocytosis or fever. A positive reaction occurs with considerable regularity in the following conditions: Infection with pyogenic organisms, toxemia of bacterial origin, non-bacterial toxemia (uremia), disturbances of respiration and grave anemia, both primary and secondary. Locke and Cabot have never found the reaction in pleurisy, rheumatism, extra-uterine pregnancy, alcoholism, abscesses with free drainage, lead poisoning, early malignant disease, nervous conditions and tuberculosis when uncomplicated by secondary infection.

Myelotoxic Serum.—To the list of toxic serums, in which are included the cardiotoxic serum of Centanni, the leucotoxic of Metchnikoff and Besredka, etc., G. Sulli (La Riforma Medica, Jan. 16 and 17, 1902) has added a myelotoxic serum. The method of its production was as follows: The medullary substance was aseptically extracted from the femur of a rabbit; this was deposited in a pocket which had been made in the subcutaneous tissue of a dog, in the lumbar region a few centimeters external to the vertebral column; the wound was sutured and a dressing applied, due asepsis being observed. After six days, the dog was subjected to the same operation upon the opposite side of the vertebral column, also in the lumbar region. Six days after the second operation the blood was extracted from the carotid artery of the dog, and the serum injected into the subcutaneous tissue of a rabbit, 5 c.c. to each kilogram of the latter's weight being used. The injections were repeated daily, in the same dose, for eight days. The only noticeable effect of this treatment was progressive emaciation. Two days after the last injection, the rabbit was killed; and upon microscopical examination the medullary cellular elements showed marked degenerative reaction to the serum. Carrying the experiment further, the author produced an antimyelotoxic serum by injecting into a rabbit myelotoxic serum for eight consecutive days, 8 c.c. to the kilogram being used. On the ninth day the blood, now presumably antimyelotoxic, was abstracted from the abdominal aorta of the rabbit. Another rabbit received an injection of 5 c.c. of myelotoxic serum, followed by an injection of double the quantity of antimyelotoxic, which had been heated to 55° C. in order to destroy the alexins. Ten days after the first injection, the rabbit was killed, and upon microscopical examination the medullary cells were found free from degenerative change.

Cytoprecipitins.—This subject is exhaustively treated in a series of articles by E. Centanni (La Riforma Medica, Dec. 21 and 23, 1901, Jan. 8 and 10, 1902). Solution of the following questions was sought through animal experimentation: (1) Do cytoprecipitins exist in normal individuals? (2) Are they formed through vaccination with cellular elements? (3) Do they occur in the spontaneous absorption of pathological tissues? (4) Have they specific characteristics through which a differential diagnosis of the agents producing them could be made? The first question was answered in the negative through absence of the phenomenon of precipitation after contact of the healthy tissue of an animal with serum extracted from its own organism; hence it is concluded that physiological life goes on without the presence of autocytoprecipitins in the blood. A negative result followed contact of serum from one animal with the healthy tissue of another of the same species (isocytoprecipitins). The same experiment with animals of different species was negative (heterocytoprecipitins). Exception must be made to the above statements in a few instances, but the occasional precipitate observed could be distinguished from a pathological precipitate by the pulverulent rather than flocculent character of the former, its scant quantity, and by the fact that the supernatant fluid did not clarify. The solution of the second question was sought through vaccination with toxic serums; leuco-, nephro-, cardio- and hemotoxic serums being used. In the case of the leucotoxic serum, five vaccinations were practised and serum was withdrawn after each; precipitation occurred in varying degrees, being very abundant after the fifth vaccination. The reagent employed was the medullary plasma from the femur of a rabbit. Experiments with other toxic serums also yielded more or less marked reaction. The conclusion is drawn that a cytoprecipitin resulting from vaccination with cellular elements can be demonstrated, though not invariably. The question of cytoprecipitins in pathological processes was next taken up; the tissues of subjects who had succumbed to phthisis, hepatitis, etc., were used, as well as experimental laboratory material. Diseased human tissue yielded a constant and abundant precipitate upon addition of serum; the results were less marked with laboratory material. A positive answer to the fourth question cannot yet, in the author's opinion, be given, though some indications point to an affirmative solution.

Intestinal and Amyloid Disease in Tuberculosis.—A careful analysis of over 6,000 autopsies conducted under the supervision of F. W. Zahn (Münch. med. Woch., Jan. 14, 1902) showed that in 32½ per cent. tuberculosis was present, and of these 92 per cent. belonged to the active and 8 per cent. to the latent type. Concerning the distribution of the process in the different organs the following figures were obtained: The lungs were involved in 80.7 per cent., the bones and joints in 3.2 per cent., the urogenital organs in 2.2 per cent., the suprarenal in 1.1 per cent., the brain in 0.3 per cent., and the intestines primarily in 2.3 per cent. Intestinal lesions were found much more frequently as a consequence of a focus in the lungs, to wit, in 63.2 per cent. of all active pulmonary cases. This is no doubt owing to gastric changes, such as acute parenchymatous and chronic interstitial processes, glandular atrophy and amyloid degeneration which so frequently are found with pulmonary tuberculosis and which permit the bacilli to reach the gut in a still active condition. Marked amyloid changes were found in only 1.6 per cent. of all autopsies.

Agglutination Test in Tuberculosis.—The agglutination test of Arloing and Courmont was tried in 256 cases by E. Romberg (Münch. med. Woch., Jan., 1902) in order to determine if a positive reaction in apparently healthy persons shows an active latent tuberculosis and if a negative reaction can also be caused by a latent process turning inactive. The result the author arrives at is that considerably more clinical and anatomical data must be gathered before the question can be decided. The reaction was always negative in those cases in which tuberculosis was most apt to be absent, namely, in the newly-born. When tuberculosis was clinically

present, agglutination occurred in 80 per cent., the remaining 20 per cent. consisting of severe and progressive cases of phthisis or of inactive forms. In 102 patients above fourteen years of age without any evident signs, the reaction was positive in 62.7 per cent. Whatever the ultimate conclusion may be, it follows that the serum reaction does not aid in the early diagnosis of manifest tuberculosis.

SURGERY.

Management of the Anesthetic in Operations on the Respiratory Tract.—If a cone or inhaler be used in operations about the nose or mouth the etherizing and the operation cannot very well be carried on together. H. P. Mosher (Boston Med. & Surg. Jour., Jan. 23, 1902) describes an apparatus which has been used successfully by Dr. T. Fillebrown and Dr. M. F. Rogers in cleft palate operations for the past three years. It is based upon the familiar principle of forcing ether vapor through a tube. A stream of ether vapor plays constantly over the patient's mouth. A water-bath keeps the ether from freezing in the bottle in which it is vaporized and the ether is forced through the tube and into the patient's mouth by a bellows. A valve in the stopper of the ether bottle gives the anesthetist a simple method of administering any proportion of ether and air desired. The water-bath is kept warm by a shielded alcohol lamp. The apparatus is useful in adenoid work. In such work chloroform is dangerous and nitrous oxide gas alone does not give a sufficiently long working period for the nice cleaning of the mouths of the Eustachian tubes. If gas is given for an extended period the resulting blueness is very disquieting, for in these operations there is always danger of getting blood in the trachea, and one of the signs of this dangerous complication is marked and persistent blueness. The upright position affords the best illumination of the parts to be operated on in adenoid and similar work; in this position, also, bleeding is less.

Surgery of the Skull and Contents.—As in the operative treatment of abdominal and thoracic affections aseptic in contradistinction from antiseptic methods have led to a great reduction of mortality, so, too, in dealing with the brain, its membranes and bony support, a decided advance has been made in virtue of the same improved technic. J. S. McArdle (Med. Press & Circ., Dec. 25, 1901) says that even in modern practice contemptuous disregard is shown for the method adopted in the treatment of compound fractures of the skull. Death certainly results in most of the cases through septic meningitis. If in fracture of the long bones it be necessary to deal vigorously with the parts exposed to infection, it stands to reason that in managing fractures which open up the diploe and expose the dura the most vigorous precautions should always be taken, first, in cleansing the wound and, second, in securing free drainage. The more radical and thorough the surgical procedure adopted the better will be the result. In injuries of the skull in which infection is absent but in which there is great intracranial tension, the latter may of itself do great damage to the brain if continued too long. There ought to be no hesitation as to the method of treatment, which ought to be the same here as elsewhere in the body. In cases of fever many patients may pass into a state of coma from intracranial pressure alone after the general tissues of the body have practically overcome the infecting germs. Why should there be in such cases any hesitation about relieving the brain and spinal cord of the products of microbic action? In syphilitic, alcoholic and other diseases which cause intracranial tension the brain should be relieved surgically rather than medically. Drainage when necessary must be free. Many patients seem hopeless on the table, but when so placed that drainage is perfect they soon recover. In washing the field of operation such fluids as carbolic acid and bichloride of mercury must be avoided.

Subserous Appendectomy.—The methods of caring for the stump of the appendix seem to be without end. Many of them lack the common sense of good surgical procedure. Under this heading the subserous method may be classed, because it does not take account of the fact that the peritoneum may be the seat of numerous virulent germs in appendicitis, although to the naked eye it may appear to be comparatively healthy. In a purely catarrhal appendicitis it probably finds its best field. Dr. Vignard (Rev. d. Chir., Dec. 10, 1901) describes the technic as follows: After the cecum is exposed and drawn out of the wound with the appendix, the tip of the latter is seized with forceps and the organ stretched out by an assistant. About one inch from the base of the appendix the peritoneum is cut through in a circular manner and then the peritoneum is stripped back to the base of the organ. At this point a ligature is placed and the appendix removed. The stump is appropriately treated and then the wide sleeve of the peritoneum, previously described, is drawn forward like a sheath over the stump and there closed by stitches or by ligature.

Treatment of Congenital Cleft Palate by Mechanical Appliances.—The impairment of the normal voice is the only functional disorder resulting from congenital cleft palate which in the opinion of G. E. Raymond (Boston Med. & Surg. Jour., Feb. 6, 1902) justifies any attempt at restoration. The inability of the infant to swallow is overcome by the nimble tongue long before the child is old enough for either an operation or an appliance. Raymond believes that perfect speech has never been obtained in these cases by a surgical operation. Mere closure of the cleft is one thing; a physiological palate is quite another. When a case is operated on in early childhood the development of the surgical palate is not commensurate with the growth of the neighboring structures of the mouth and throat; hence what is gained in childhood may be lost later. When an appliance is used it can at any time be replaced by another if the development of the patient demands the change. Raymond has obtained satisfactory results by the use of mechanical appliances in a series of cases which he describes.

Fractures of Upper Third of Femur.—The tilting forward of the upper fragment in fractures of the upper third of the femur cannot be prevented; successful treatment must, therefore, recognize this fact and be influenced accordingly. The lower fragment must be placed in the line indicated by the position of the upper fragment—that is, in a flexed position—and, as the upper fragment is usually displaced outward also to some extent, the limb should be slightly abducted. Since displacement results principally from muscular contraction, extension is strongly indicated and with coaptation splints may secure perfect immobilization. R. A. Hibbs (N. Y. Med. Jour., Feb. 1, 1902) recommends the long traction hip splint for these purposes, such as is used in the treatment of hip disease. By this means, extension is always constant and direct, and may be made to a degree that will absolutely control the muscular spasm. Changes in the position of the patient do not affect it, nor does its force depend upon the weight of the patient. Coaptation splints are of minor importance and can be easily made by attaching straps to the strong iron rod along the upper part of the thigh. An anesthetic is necessary to apply properly

the splint. The adhesive plaster should run up to the fracture and considerable extension should be exerted during the first few days. The leg is raised to an angle of about 135°, but after the splint is applied movements of the spine may be allowed without interfering with the position of the fragments. The perineal straps should be removed each day, one at a time, and the parts bathed and powdered.

Syphilis of Rectum and Anus.—A common mistake, when a physician doses a patient with mercury and diarrhea supervenes, is to presume at once that the cause of the diarrhea is the medicine. J. A. HAWKINS (International Med. Mag., Jan., 1902) emphasizes the fact that in syphilis the rectum should be examined as conscientiously as the eyes, throat and glandular system, for frequently the diarrhea will be found to be a part of the disease. Chancres are rare, are generally found below the internal sphincter and must be attributed to unnatural intercourse. The most common affection is the condyloma, which, either singly or in groups, occasions considerable distress from the burning and discharge; it is frequently mistaken for hemorrhoids. Mucous papules, too, are not rare, are generally situated on the posterior surface of the bowel, and, though they often are ulcerated, only exceptionally cause pain, discharge or bleeding. Gummata may lead to ulceration, obstruction or subsequent stenoses. The treatment of syphilis of the rectum does not differ from that of syphilis in general, with the addition of such surgical interference as may be necessary. Thus, for stenosis, linear proctotomy with subsequent use of bougies is best, though a persisting ulceration often necessitates a subsequent colostomy, preferably in the left inginual region.

Progress in Radiography.—Many and varied are the advances in radiography to be noted during the past year, not only in the apparatus used but also in its wider application to both surgical and medical disorders. Among the improvements in the instruments A. SCHONBERG (Münch. med. Woch., Jan. 21, 1902) mentions the electrolytical interrupter, the orthodiagraph of Moritz which permits the use of the perpendicular ray, and Cowl's apparatus by means of which radiographs can be taken in different stages of respiration. The use of leaden diaphragms permits investigation of such structures as the cervical vertebræ, the head of the humerus, mastoid cells, the interior of the skull, etc. Apparatus for stereoscopic pictures have gained considerable popularity and are invaluable for the examination of congenital luxations. An entirely new field is the photographing of teeth and such deep-seated structures as the antrum of Highmore and frontal sinuses. Now as before the most useful field for the X-rays is to be found in the examination of fractures, especially if two pictures in different planes are taken, and it is only in very obese people and in the epiphyseal separations of children that difficulties may be experienced. Little new is to be said concerning dislocations, except that more accurate reduction is possible. Osteomyelitic foci and sequestra yield very satisfactory pictures, especially in the bones that are not readily accessible to direct palpation; the early stages of tuberculosis cannot, however, be diagnosed, since the process here begins in the bone-marrow, while syphilis and tumors of bone are generally easy to discern. Hardly any advancement has been made in the localization of foreign bodies, nor have the Röntgen rays done much in ophthalmology or in laryngology. An extremely interesting and valuable but difficult matter is the detection of calculi. For stones in the bladder the method is valueless except in the very rare cases in children and in cystoscopy there is a more reliable method of examination. Not much more encouragement can be given in the diagnosis of gall-stones, but it is in detecting renal stones that the X-rays are often of the greatest help, provided the stones do not consist of uric acid, cystin or xanthin, provided they are larger than a bean and provided the patient is not very corpulent. In the examination of accident cases much information can be gained, but care must be exercised not to consider such structures as supernumerary sesamoid bones as fragments of bones resulting from injury. Turning now to internal medicine, it will be found that here also much progress has been made, though the results on the whole are far less gratifying, for the constant movement which the thoracic and abdominal organs undergo makes it clear that sharp plates are only exceptional. For tuberculosis, radiography can be considered only an adjunct to the usual methods of examination and it would be a mistake to base a diagnosis upon the appearance of the plate alone, though valuable evidence as to the amount of infiltrated and destroyed tissue can be obtained and cavities can generally be identified as such. When the process is situated deeply in the lung, as in hemorrhages, infections, abscesses, tumors and echinococcus, percussion and auscultation often yield unreliable data and much may be expected from the Röntgen rays, which are also serviceable for the investigation of the position and amount of fluid in the various forms of pleurisy with or without air. The position of the diaphragm, limited unilateral excursions of this muscle and the presence of a diaphragmatic hernia can be sometimes recognized. The exact determination of the heart boundaries has been rendered possible by the orthodiagraph, even in cases of advanced emphysema or in women with large breasts, on whom percussion cannot be employed, and by means of no other method can the position and size of the right auricle be ascertained so well. In the following other conditions the Röntgen rays are of inestimable value: Aortic aneurisms, especially with the aid of oblique transillumination, mediastinal tumors, stenoses and diverticula of the esophagus, which show clearly when the patient is directed to swallow a wafer with bismuth, and in the various changes in size and position of the stomach, when with the aid of bismuth the lower border becomes distinct. The detection of drugs, such as arsenic, in the stomach and intestines is a possibility which is being diligently investigated. Last, but not least, is the value of Röntgen's wonderful discovery from a therapeutic point of view, especially in lupus, scrofuloderma, lupus erythematodes, eczema, rosacea, acne, prurigo, sycosis and favus.

Adhesion Breaking.—Adhesions within joints are always troublesome and their cure determines the degree of satisfaction which the patient feels in his case. G. W. ORD (Lancet, Jan. 12, 1902) states that to break down adhesions without an anesthetic is often a matter of necessity. The passive motion which follows the breaking down is always a very painful proceeding and frequently takes the form of exquisite and repeated agony. The pain may last a long time after the manipulation has stopped, so that the patient dreads the appearance of the physician for the treatment. The method which he recommends consists in fixing the part above the stiff joint by means of the surgeon's left hand to the bed or the table and then quickly causing the movement in the joint. Adhesions in the wrists, shoulders and knees are too often broken down without getting the patient into a good position. It is a mistake to treat adhesions of the shoulder or the wrist with the patient sitting or standing. A large amount of pain is caused with comparatively little result, for the reason that the patient is in the best possible position to resist. With regard to the knee-joint the muscles around it are so strong that the advantages of his

method are at once apparent. In detail his technic is the following: For the shoulder-joint manipulations, the surgeon stands behind the patient's head, while the latter lies flat on his back on a hard mattress. The surgeon's hand is placed flat on the clavicle of the affected side, pinning the patient to the mattress or the table. The right hand of the surgeon then takes the extremity at the elbow and raises the latter joint until it is on a level with the shoulder joint. In the case of the wrist the patient's forearm is placed on the table in the supine position. The surgeon's left hand holds the forearm to the table, while with his right he grasps and flexes the patient's hand quickly to a right angle. Finger-joints are treated in the same way. The hand is pinned down to the table with its palm upward and the manipulation is carried forward with the right hand of the surgeon. In treating the knee the patient lies prone upon the bed and the surgeon's left hand grasps the thigh just above the knee and holds it firmly to the table or bed. The right hand then seizes the leg just above the ankle and quickly makes a flexion at the knee. There must always be some pain when adhesions are broken down, but this quick method makes it momentary. A large amount of joint movement is obtained at once by means of far less force than would otherwise be necessary. The resistance of the patient, which in other methods is a large factor, becomes a very small one. The duration of the after-treatment is also rendered less because at the first effort a larger amount of mobility is obtained.

Amputation and Sepsis.—The question as to whether amputation of a limb is a justifiable operation in general sepsis following a local process is discussed in two articles by H. Brauser and H. Doerfler (Münch. med. Woch., Jan. 21, 1902). The former is of the opinion that amputation is indicated as an early operation in those severe cases of sepsis in which, despite free incision, the process rapidly extends and life is in imminent danger, and as a late operation when wide incisions have also been made, but no reactive powers on the part of the individual are noticed and the local and general symptoms continue unabated. The second author, on the other hand, finds that in the first set of cases, usually induced by the bacillus of malignant edema, amputation never stays death, while in the second set it is sufficient to incise up to the limits of the inflammatory edema, and to increase these incisions if the edema is found to spread, even if this be up to the trunk. Numerous cases are cited in which even cocci were found in the blood and metastatic foci had already formed and in which this procedure was life-saving without the loss of a limb.

Hernia in Infants.—Great anatomical defects in the walls of the trunk are usually the primary cause of hernia in infants. J. D. Rice (Lancet, Jan. 4, 1902) reports a case of strangulated inguinal hernia in an infant nineteen days old with operation and recovery. On examination he found a tense swelling partly filling the left side of the scrotum and the inguinal canal, without impulse when the child cried, and with a doubtful or dull note on percussion. The skin over it showed edema and redness. The subcutaneous tissues were also involved. The swelling was absolutely irreducible, very painful and tender. There was no vomiting and the general condition of the patient was so good that an evaporating lotion was prescribed and the child put to bed, with its buttocks on a pillow, with the diagnosis of a possible hydrocele of the cord. The next day, however, all the bad symptoms appeared—violent vomiting, blood and mucus with the stools, and prostration. At the operation, which was done as soon as possible, a very tight stricture at the upper end of the inguinal canal was found. When this was divided the gut slipped back into the abdomen. The intestine was dark in color, but not black. The wound was closed in the usual method and the child, although in a bad condition on the operating-table, soon rallied and was feeding at the breast a few hours after the operation. Convalescence was uninterrupted and at the end of two weeks the wound had entirely healed by first intention. Nine weeks after the operation there was only a small scar present without bulging even when the child cried.

Vesical Calculi.—The promptness with which a diagnosis of stone in the bladder is made is an important element in the prognosis. K. Dohrn (Deut. Z'schr. f. Chir., Dec., 1901) says that if examination with a stone-searcher or with a cystoscope is impossible, either through stricture of the urethra or enlargement of the prostate gland, the X-rays should always be resorted to. In fact in all cases a radiogram would be advisable because it shows at one sitting such features as the size, position and number of the stones. Unfortunately the great value of the X-rays for recognizing stones is up to the present not yet appreciated. The difficulty seems to be in the general ignorance of the fact that the kind of stone influences the picture. Phosphatic stones are the most penetrable and therefore give the poorest picture. Uric-acid stones are less penetrable and the oxalic acid stones are the most opaque. While authors differ as to this precise relationship, in the main this is the best classification with reference to shadows they cast on the plate. Another important point is the length of exposure, which in general terms should be short, especially with the more easily penetrable bodies. The experience of the writer in this last particular is that an average exposure of two and one-half minutes is enough. On the other hand, there are some cases in which a shorter and others in which a longer exposure is necessary; so that the difference between them would be represented by one minute for the shortest and two minutes for the longer times. A very important field in which a radiograph is serviceable is that in detecting stones in diverticula of the bladder. It is precisely in this class of cases that other means of diagnosis are apt to fail, leaving this method in sole possession of the field. The author is certain that, as knowledge of the X-ray increases, the frequency with which it is available for medical purposes will be increased.

Interstitial Hernia.—This form of hernia is so rarely encountered that many operators overlook its essential nature when in the hurry of an operation they unexpectedly come upon it. P. Berger (Rev. de Chir., Jan., 1902) presents a long discourse on the subject and advances the following propositions concerning it: It is necessary to apply in man the term inguino-interstitial herniæ to those congenital ruptures which are complicated by ectopia testis and in which the hernia itself extends into the thickness of the abdominal wall, winding more or less among the musculo-aponeurotic planes. Such herniæ present two principal varieties—in one it is distinctly parietal, and in the other in addition to being intraparietal it is scrotal also, through a secondary sac or diverticulum which passes through the external inguinal canal and ring. The intraparietal part of the sac is for the most part a finger-like prolongation or process which turns outward toward the anterior superior spine of the ilium. It is usually pointed much like the finger of a glove, has all the characteristics of a congenital sac and usually contains the viscus because the scrotal prolongation is usually so narrow that it will not admit it. The external inguinal ring is usually closed excepting in the cases in which a scrotal sac exists as well as an interstitial sac. Sometimes it is sufficiently patent to permit the passage of the testis. The internal inguinal ring is often placed a little higher and a little farther out nearer the anterior

superior iliac spine than is usually the case. It presents therefore a congenital displacement which has been so described by Meinhardt-Schmidt. It is necessary to distinguish with care these cases from those in which the deep inguinal ring is twisted and displaced inward toward the abdominal cavity, chiefly by efforts at reduction of the hernia. In the space between these two rings the intraparietal sac usually spreads out between the aponeurosis of the external oblique muscle and the transversalis fascia. It is not unusual, however, to find its anterior surface covered by the internal oblique fascia. Sometimes the sac sends forward a deep prolongation between the transversalis muscle and the transversalis fascia. These facts make this kind of hernia difficult to distinguish from inguino-interstital hernia complicated by a properitoneal hernia. The testis occupies a varying position in the hernia sac. Sometimes it is absent, thus complicating the hernia by a cryptorchidia. In the largest number of cases the testis is within the inguinal canal, sometimes fixed near the internal abdominal ring, more commonly just inside of it. It may also be situated lower down. Occasionally it is found at the external abdominal ring, which it then closes as a cork does a bottle. When the hernia is intraparietal and scrotal at the same time the testis may be found in the scrotal diverticulum of the sac. It may have this position through being slowly pushed forward. The organ usually presents a marked degree of arrested development. There are also at the same time a marked atrophy and a manifest weakening of the muscular planes and fibrous tissue of the abdominal wall. The cord is often short and adherent. Many bands of fibrous and muscular tissue serve to hold it down and they must be divided before it can be passed into the scrotum. Sometimes the cord is too short to permit this at all. It is certain that in many cases which present the characteristics of inguino-interstitial herniæ the testis in a state of intra-inguinal ectopia is situated in a sheath of its own entirely distinct from the sac of the hernia. There is then the rare condition of a proper tunica vaginalis testis, while the hernia is both intraparietal and scrotal in addition. In very rare instances inguino-interstitial herniæ which closely resemble the same class in men are found in women. The same two classes of intraparietal herniæ are found; one in which the type is pure with the sac confined to the muscles of the abdomen, and the other in which the type is mixed, adding to the foregoing a prolongation through the external abdominal ring into the labium major. The treatment of these herniæ should always be operative because it is almost impossible to retain them with a truss. The hernia should be approached by an incision of the external oblique muscle parallel with its fibers. The testis as a rule should not be retained. The one exception is when it is in a healthy condition and may be passed into and easily retained within the scrotum where it belongs. It would be better when possible to save it in children and youths who may by later development overcome its ectopia, but after the twenty-fifth year it had best be removed. In repairing the abdominal wall the surgeon will meet his greatest difficulties. If the method of Bassini appears to be insufficient to cover the opening it is best to reinforce that method by taking a flap of fibers from the anterior wall of the sheath of the rectus, turning it outward and downward over the inguinal canal and sewing it in place there.

Cancer of the Lip.—In no part of the body as in the face is cancer so slow in progress. Consequently its surgical treatment is more hopeful than elsewhere. L. J. JANOWSKY (Arch. f. klin. Chir., 1902, B. 65, H. 2) gives the following points as to the present position of the surgical world toward this disease: (1) Radical operation for cancer of the lip belongs to the class of safe surgical procedures. The healing of these wounds is so favorable that by far the greatest number of them are well in from nine to fifteen days. (2) The lymphatic glands in the submental and submaxillary region should always be removed. The latter must especially be sought for and ablated at the same time as the submental region is opened, because it is in this space that most of the secondary deposits occur. (3) When necessity indicates, no one should hesitate to resect the lower jaw because by so doing a radical cure is often obtained which would otherwise fail. (4) The lymphatic glands are usually attacked in cancer of the lip rather early, sometimes even after two or three months. But in a large number of cases even the presence of such inflammation does not shut out the chance of a radical cure. In some cases in which the glands are not apparently involved a recurrence in them will occur apparently almost as actively as if they are clinically attacked. (5) Favorable results of operation may be looked for in about forty-nine per cent. of the cases. (6) Recurrences appear in the majority of cases within six months after the operation, some during the first year, and a few between the first and the second years. (7) As a rule the return of the disease begins at the seat of the original lesions or in the submental space. (8) The duration of the process has a direct bearing on the result of the operation. If the cancer is a rapidly progressing one, the outlook is necessarily bad, but in those that grow slowly an operation may be undertaken sometimes a year or two afterward and still be successful. (9) Advanced age of the patient is hardly a contraindication to the operation, because good results have been obtained at an age of from sixty to seventy years. (10) Secondary operations upon return of the cancer may be undertaken; sometimes they will prolong the life of the patient, but necessarily only for a short time. (11) Cancer of the upper lip is recorded nineteen times less than cancer of the lower lip. In women it is ten times less common than in men. This is in the author's record of one hundred and seventy-eight cases. In 12 of his series, it was impossible to find that social position or occupation had any direct bearing on the disease. Advanced age (sixty to seventy years) seemed to be the greatest cause. The rapidly fatal cases apparently make up about twenty-five per cent. of the records; the slower processes, fifteen per cent., and the other sixty per cent. may be called the mean class.

Ascites.—This symptom of several conditions may be entirely removable by surgical means. H. ITO and K. OMI (Deutsche Z'schrift f. Chir., Dec., 1901) have been experimenting upon animals as to the possible causes of ascites and its remedy by surgical means. From the experiments they drew the following conclusions: Dogs as a rule perish in a short time with the symptoms of bleeding if their portal vein be suddenly and totally tied off. This happens whether the ligature is placed just above or just below the juncture of this vein with the gastro-splenic vein. With repeated progressive tying of the vein step by step toward the liver, beginning at its small tributaries of origin, animals may recover until the confluence of the two veins, as just stated, is reached. As soon as the ligature is placed beyond this point they die, but usually without such severe symptoms as when the vein is tied off at this point at the first sitting. If the omentum be caused to adhere to the abdominal wall and then after a while the vein is tied, some of the animals will perish and some will not. The same thing occurs if the omentum is similarly adherent outside of the peritoneal cavity. It seems therefore that it is not the location of the ligature but the extent of adhesions between

the omentum or other abdominal organs and the wall of the abdomen which determines whether or not the animal lives or dies. He lives if the collateral circulation be sufficiently active through these adhesions. The formation of adhesions and the inclusion of collateral veins within them are what occur when the omentum is transplanted in this wise. It is interesting to note that animals which recover from the last procedure remain well for months afterward and often increase in weight. The clinical application of these experiments is that in ascites the surgeon should seek to cause a widespread general adhesion as far as possible between the organs of the abdomen and the wall and between the organs themselves. The fixation of the omentum is really only a part of the whole process. It appears to make little difference whether the omentum is stitched to the wall within or without the peritoneal cavity. The important thing is that the intestines, the liver and the spleen should also be made widely adherent to the wall. Perhaps the most active means of promoting this adhesion would be a general tamponade of the whole abdominal cavity by means of a very long strip of sterile gauze, which should be tucked carefully into the pockets and angles of the peritoneal cavity. After twenty-four hours the packing could be removed.

HYGIENE.

Propagation of Yellow-Fever by Mosquitoes.—The presentation of collected statistics and observations on this subject by the chief sanitary officer of Havana, W. C. Gorgas (Phil. Med. Jour., Jan. 4, 1902), forms a strong argument in favor of the view that the *Stegomyia* mosquito is the only means of conveying yellow fever and that fomites can no longer be considered as carriers. Yellow fever, which has been endemic in Havana for 150 years, caused an average of 410 deaths from the first of April to the first of December, for the years since 1899, with a maximum of 1,175 for the year 1896 and a minimum of 79 for 1899, but this year only caused five deaths, although the chances were increased by the presence of a greater number of non-immunes than ever before. Although at first some precautions were taken against fomites, these have all been abandoned, including rigid quarantine and disinfection of fabrics and clothing. Attention was directed entirely to the mosquito, the house of an infected patient was screened, as many mosquitoes as possible were killed, and in addition oil was poured on all suspected breeding-places. General sanitation is in addition most important.

THERAPEUTICS.

Gelatin in Melena.—The hemostatic properties of gelatin show themselves better perhaps in melena neonatorum than in any other condition. A. Holtschmidt (Münch. med. Woch., Jan. 7, 1902) finds that with the old method of treatment 50 per cent. of the children are lost, while the injections save nearly all. It is better to inject a fairly strong 2 per cent. solution, since one can readily control its sterility, owing to the fact that it solidifies on cooling and any bacterial growth would readily show itself. Fifteen c.c. of the solution which have been kept on a water-bath for from five to six hours are injected into the subcutaneous tissues of the breast or thighs, generally in two places to prevent undue stretching of the skin. If necessary, the procedure may be repeated several times. Bad after-effects were never seen, not even a rise of temperature.

The Serum of Trunecek.—The inorganic serum introduced by Trunecek as a valuable therapeutic agent in arteriosclerosis contains all of the alkaline salts normally present in human blood-serum; the solution is concentrated, but the relative proportions of its alkaline constituents are maintained. The technic of its clinical use is described by Leopold Levi (La Presse Méd., Jan. 15, 1902). Trunecek begins by injecting 1 cubic centimeter of the solution, and the injections are gradually increased till 5 to 7 c.c. are given daily. The injections are given alternately on the left and right sides, the forearm and gluteal region being favorite sites. The remedy is applicable to cases of sclerosis of the great vessels, arterial cachexia, cerebral arteriosclerosis, and chronic rheumatism. Levi reports a case similar to those previously cited by Trunecek, characterized by attacks resembling angina pectoris, but occurring nightly for many months. After a single injection of inorganic serum relief was obtained. Satisfactory results were also obtained in cases of cerebral arteriosclerosis with symptoms limited to one side of the body. Not only were local manifestations of the disease, both sensory and motor, greatly modified, but general symptoms were likewise controlled.

Cure of Cancer of the Esophagus by Cancroine.—Cancroine is a toxin of undefined chemical composition isolated from cancerous growths. In its physiological properties it is identical with neurine, a toxic base obtained from fresh cadaveric tissues. It is maintained by A. Adamkiewicz (La Presse Méd., Jan. 22, 1902, that when injected into the circulation of cancerous subjects, cancroine exercises a specific action on the malignant growth, producing a necrosis of the carcinomatous elements with or without inflammatory reaction, with resorption and elimination of the necrotic elements. Adamkiewicz believes that he has rendered a double service to science and humanity in publishing the results obtained by him in the treatment of cases of cancer by cancroine. Four recent cases are described, all of them purporting to be cases of cancer of the esophagus. The first patient was a man sixty-six years of age, with a three-months' history of increasing dysphasia and emaciation. Even small bougies were obstructed at the lower end of the esophagus, 42 cm. from the dental arch. Six days of treatment by injections of cancroine produced a notable functional improvement and at the end of this period a sound of 5 mm. diameter could be introduced into the stomach. As the disintegration of epithelial cells in such a brief period is inconceivable, Adamkiewicz believes that carcinomatous growths are made up of protozoa. In a second case symptoms of stenosis were rapidly disappearing under the influence of injections of cancroine when the treatment was interrupted. Dysphagia at once returned. A short time afterward the injections were resumed and within two days an amelioration of the patient's condition was re-established.

DERMATOLOGY.

Oidiomycosis of the Skin and Its Fungi.—Since attention was called to the existence of blastomycetic dermatitis in Chicago and vicinity by Gilchrist the number of cases observed has rapidly multiplied. As the result of a detailed study of a number of such cases H. T. Ricketts (Jour. Med. Research, Dec., 1902) concludes that the so-called protozoic disease of Posadas, Wernicke and others, Busse's and Curtis' saccharomycosis hominis, and Gilchrist's blastomycetic dermatitis are various manifestations of the same disease. The condition in the skin possesses constant clinical and histological characteristics which separate it positively from all other skin diseases, particularly verruca, tuberculosis, carcinoma and syphilis. The organisms isolated from various cases differ from each other in minor respects, but are so closely related morphologically and biologically as to justify their inclusion in a common genus. They are thus analogous in a

pathogenic sense to the fungi which cause actinomycosis and to those causing trichophytosis. The variations among the organisms allow the recognition of three morphological types: (1) Blastomycetoid (yeast-like); (2) oidium-like; (3) hypomycetoid. There are two histological forms of the disease in the skin, the eosinophilous and the non-esinophilous, the former being associated with the mold form of the organism. Oidiomycosis is an appropriate name for the conditions caused by the organisms and oidiomycosis cutis for the disease as it occurs in the skin.

MEDICINE.

Chorea and Helminthiasis.—The obscurity in which the pathogenesis of chorea lies is evidenced by the many theories concerning it; its origin has been variously considered as rheumatic, nervous or infectious. M. de Luna (Gazz. degli Osped., Jan. 12, 1902) has noted a certain relation between helminthiasis and chorea. In a case recently observed, microscopical examination revealed ova in the feces, and the administration of anthelmintics was followed by the expulsion of three ascarides and many segments of tinea solium, with the result that there was entire abolition of choreic symptoms.

Membranous Colitis.—Membranous colitis is a disease which in most text-books has generally been dismissed with a few words relative to the "membranes." That it is, however, a disease of very wide distribution and often of great diagnostic importance is growing to be more and more thoroughly appreciated, in consequence especially of the efforts of the latter-day functional school in medicine. The subject has been treated in his characteristically broad, yet thorough, fashion by M. Foster (Edin. Med. Jour., Feb., 1902). The name of the disease is, in his opinion, to a certain extent a misnomer, since literally it embraces only those typical and unmistakable cases in which true fibrinous casts are passed from the bowl, whereas these represent only the *terminal* stage of the disease. The earlier stages of such cases, however, and milder types, also, of the affection, illustrate every variety of mucous discharge; all of these conditions, therefore, are to be considered as having a common clinical basis. There are three cardinal symptoms of the disease: Passage of mucus, irregularity of the bowels, and abdominal pains. The distinguishing feature of the disease really consists in the character of the stools. The mucus may be present in every variety of form.

In the class of milder cases there are scybalous masses. Their presence often leads to an incorrect diagnosis, the case being considered as one of catarrhal colitis whereas it probably is a case belonging to the class of mucous colitis. The feces may be merely coated with a glairy film; such cases are very apt to be mistaken for examples of mucous colitis and therefore wrongly treated. In the more advanced stages of the disease, mucus may be passed separately, either in small globular lumps resembling frogs' spawn, or as large solid lumps like pieces of jelly-fish. In the most marked cases, the mucus is condensed into membranes, which may be passed as annular casts of the intestine, or in loose shreds or strips. The membranes sometimes present an actual cast of the wall of the gut, in which the crypts of Lieberkühn are distinctly visible. Microscopically, these membranes consist of cells embedded in a transparent matrix, containing also phosphates, cholesterin crystals, and bacteria, the B. coli communis being in the largest proportion. In addition to mucus, in a few of these cases there is another foreign substance, namely, intestinal sand, which appears as brownish red particles, much resembling uric acid. This "sand" is rarely seen except in cases of membranous colitis, and may fairly be considered as typical of one form of the malady. As regards the stools themselves, they present no other constant characteristics. Turning to the second cardinal symptom, the majority of patients have suffered from constipation. Diarrhea occurs not infrequently, but it is of the irritative variety and does not serve to unload the bowel. Pain is at some time or other a marked symptom in most cases. It may vary in intensity from an attack of mild colic to pain of such severity as to suggest the possibility of perforation. It may take the form of erratic pains over the entire abdomen, or may be localized in the region of the ascending colon with tenderness in McBurney's point, or, finally, may mimic gastric discomfort. Very rarely it is absent. Physical examination reveals cutaneous hyperesthesia, or enteroptosis, etc., but nothing pathognomonic. Constitutional symptoms are slight. In some cases there is in each attack slight fever, the temperature during the period that membranes are being passed varying from 99° to 101°, or even 103° F. The pulse is changed only in relation to the fever or to extreme pain. During the attack, the tongue is generally coated, sometimes with thick white fur, but more commonly with a fine yellow layer. A characteristic and interesting feature of the disease is the fact that most of its victims suffer from neurasthenia, either of the moody or of the erethistic type. The nature of the disease is probably that of a secretory neurosis, finding its expression in hypersecretion of mucus, coupled with spastic constipation, whereby the mucus is molded in the colon into membranes. As has been said, sufferers from the disease are almost always neurasthenics, and the family history will generally show a marked neurotic taint. In addition, gout undoubtedly plays an indirect part in the causation of many cases. The patients are for the most part lithemic, and have the nervous instability so often seen in those derived from gouty stock. In the management of the disease, the first step should be the treatment of the neurasthenia. A proper amount of exercise should be taken, and the food should be selected with a view to eliminating all irritating constituents. To regulate the bowels, castor oil or enemata of olive oil are useful. During the attack, rest in bed and fluid diet are routine practice, and morphine may be necessary. Nerve tonics are often useful; nitrate of silver in doses of one-thirtieth of a grain is often of great service. In the more prolonged and hopeless cases, the performance of a right-sided colotomy is advocated, with a view to giving the bowel a rest. Operation should never be too long delayed, as, with all its discomforts, it affords a chance of escape from even greater miseries.

On Addison's Disease.—To determine if the blood of patients suffering from Addison's disease possesses toxic properties, J. Bruno (Münch. Med. Woch., Jan. 28, 1902) injected the blood-serum from a case of the more chronic form of the disease into frogs. A comparison of the results gives no difference between the toxicity of the patients' blood and that of normal serum. The author does not, however, consider his experiments conclusive and recommends that the blood of patients running a more acute course be tested in a similar way.

Etiology of Rachitis.—From the fact that in rachitis both the relative and the absolute weight of the thymus gland is below the normal, that the gland reaches its highest development when bone-proliferation is most active and that during this period it contains those salts which are most necessary for the building-up of osseous tissue, F. Mendel (Münch. med. Woch., Jan. 28, 1902) concludes that a close connection exists between the disease and the organ.

Viewed in this light the enlargement of the spleen might be considered a vicarious hypertrophy. Animals experimentally deprived of their thymus showed marked changes in the structure of the bones and the anemia and profuse perspiration so characteristic of rachitis could also be duplicated. Accordingly either fresh glands or the commercial tablets were tried in over 100 cases which were classified as follows: (1) Those which showed only the prodromal symptoms; (2) those in which deformity of the osseous system was the chief feature; (3) those marked by spasm of the glottis, and (4) those in which splenic enlargement was the most important sign. In all marked improvement was noted after from three to four weeks and dentition and the closure of the fontanelle proceeded satisfactorily. Unlike thyroid extract, no untoward symptoms are to be expected after even large doses.

Dyspeptic Asthma.—This term should be reserved for those cases of asthma which are free from any involvement of the chest organs and in which the affection is in distinct connection with the digestive apparatus. M. Einhorn (Jour. Amer. Med. Assoc., Feb. 1, 1902) divides these cases into two groups: (1) Those in which dyspeptic asthma appears periodically in an acute form; (2) those in which it assumes a chronic type. The first group is characterized by asthmatic attacks at more or less prolonged intervals, without apparent cause or after excesses in eating, drinking, or smoking, or after undue excitement. The attack is usually severe, often with extreme dyspnea, cyanosis, almost collapse. The second group embraces the larger number of cases and may again be divided into those in which the asthma appears soon after meals or those in which it comes on several hours later. The first class resembles and is often difficult to distinguish from angina pectoris but is more amenable to treatment directed toward the digestive apparatus. The angina, however, may be superadded and is then apparent by cardiac involvement, as indicated by the sudden appearance of albumin on the urine or irregularity of pulse, etc. Although no constant anomalies of the secretory condition of the stomach were found in his cases, yet a considerable number suffered from achylia gastrica or hyperchlorhydria, both conditions probably due to the undue irritation of the gastric mucosa. When the gastric secretion is normal it is necessary to assume a condition of hyperesthesia of the stomach to account for the cause. The so-called floating liver was also found in 17 per cent. of his cases and is also probably a factor. The treatment must be directed toward relieving any disorders of the digestive tract and also towards correcting any malpositions of the abdominal organs, principally the liver. Regular mode of life and avoidance of too much tobacco and alcohol, also of mental worry and strain, are essentials.

NEUROLOGY.

Meralgia Paresthetica.—This name is applied to a peculiar nervous disturbance manifesting itself in paresthesia, anesthesia and pain in the femoral course of the external cutaneous nerve. The paresthesia takes the form of numbness, pricking, formication, or a feeling of coldness, present, according to M. Kahane (Klin. therap. Woch., Jan. 12, 1902), in an area bounded in front by the middle of the anterior aspect of the thigh, behind by a line separating the external from the posterior surface, above by Poupart's ligament and extending below to within three or four finger-breadths above the condyles. The anesthesia shows itself subjectively by a sensation as if wool were present between the clothes and skin; objectively it is generally found to be only poorly developed, but also affects the temperature sense, though there may be hyperesthesia toward electricity. Sooner or later, pain will appear, generally after excessive use of the parts and never equaling in intensity the pain of tabes, so that such disturbances of function as limping hardly occur and a short rest causes their disappearance. Trophic disturbance, such as muscular atrophy, glossy skin, and vasomotor changes, are rare. General symptoms, more particularly inequality of the pupils and changed reflexes, have been included among the symptoms, but are more often to be ascribed to coincident, more serious nervous disease, such as tabes or general paresis. The etiology is to be found in local trauma, exposure to cold, infections, intoxications and dyscrasiæ, such as syphilis, typhoid and chronic alcoholism. Generally the patients are males between the ages of thirty and sixty years, who are obliged to stand or walk a good deal; often flat feet also are present. Two theories have been advanced to explain the condition—that of congestion of the nerve and that presupposing an active neuritis; a sufficient number of pathological examinations have not yet been made to decide the question, though the weight of evidence supports the latter. The course is chronic and intermittent, the diagnosis easy, and the treatment either medical and symptomatic or surgical by resection of the nerve.

SKIN AND GENITO-URINARY.

Ringworm.—Although ringworm of the skin is one of the easiest skin diseases to cure, rapidly disappearing under the action of almost any parasiticide, ringworm of the scalp or beard frequently taxes the ability of even the clever specialist for many months. G. T. Jackson (Med. Rec., Feb. 1, 1902) has been using a very simple but most effective remedy in these cases for two years and is highly enthusiastic over the result. A dram of the crystals of iodine is added to an ounce of goose grease and this preparation is applied to the affected areas twice a day till some redness and swelling appear. It is then applied once a day until a cure results. Goose grease seems to be an excellent penetrating excipient, but it is necessary to make sure that it is the genuine article. The hair falls out of the patch and epilation is not necessary. The first applications are apt to be a little painful for a few moments, but after that even little children do not complain of the pain. If much reaction with swelling is caused the use of the remedy can be suspended for a few days, and a salicylated oil of three-per-cent. strength can be used. As soon as the reaction subsides the iodine remedy should be resumed. Three weeks are usually sufficient to secure a cure of barber's itch and about the same time for ringworm of the scalp.

Syphilis Maligna and Syphilis Gravis.—The early appearance of numerous ulcerations over the entire surface of the body is the chief characteristic of malignant syphilis. Associated with this condition, says Lochte (Monatsh. f. prak. Derm., B. 32, No. 10) is a marked loss of strength. The patient becomes emaciated, loses his appetite, looks wretched. The painful ulcers prevent sleep and may produce fever which persists for months. The practitioner is struck by the inefficacy of the mercurial treatment in these cases. Cases of severe syphilis which approach the malignant form in virtue of their localization in vital organs or on account of their combination with other pathological conditions, or which in their specific manifestations resemble syphilis maligna, Lochte groups under the name syphilis gravis. The most dangerous chronic complication of syphilis is alcoholism. Phthisis threatens the life of the syphilitic individual doubly, for not

only does syphilis often assume a grave form when the complication exists, but the pulmonary disease makes rapid strides. Malaria and tropical anemia en- Harn- u. Sexualorgane, B. xii., H. 6) communicates age and pregnancy are also dangerous complications. None of these conditions, however, can be said positively to determine syphilis maligna.

Lesions of the Rectal Mucous Membrane as a Cause of Cystitis.—Wreden was the first to assert that lesions of the rectal mucous membrane in the vicinity of the prostate are invariably followed by cystitis, and the first to show that in cases of experimental cystitis in dogs the urine contains bacteria introduced into the rectum. Faltin (Centralbl. f. d. Krankh. d. Harn- u. Sexualorgane, B. xii., H. 6) communicates the results of his experiments on 100 dogs as follows: A lesion of the rectum in the vicinity of the prostate, whether superficial or deep, is not followed by cystitis, nor are intestinal bacteria found in the urine in these cases, provided the bladder at the outset is free from disease, and provided also that the rectal lesion is not followed by either general systemic infection or peritonitis. Serious lesions of the rectum may very readily produce general infection, however. Omitting cases of sepsis. Faltin was able to discover cystitis in only one of his many cases, and in but one case was there even a transient bacteriuria. Microscopic examination showed that following the slightest trauma of the epithelial surface of the rectum, numerous bacteria made their way promptly into the lymphatic spaces of the tissue surrounding the rectum, bladder, prostate and seminal vesicles. If the bladder be injured by retention at this stage, the pathogenic germs which are sojourning in the neighborhood may succeed in finding entrance and may thus set up a cystitis.

Gauging Vesical Capacity.—A method for determining the bladder capacity in patients in whom the nervous element is a serious factor for consideration —cases distinguished clinically by a lessened frequency of micturition at night—and in certain conditions in which rest is productive of similar improvement in symptoms, is submitted by G. F. Lydston (Jour. Amer. Med. Assoc., Feb. 8, 1902). This method does not err by proving only the capacity of the bladder while in hyperdistention. The patient is instructed to drink moderately of pure water during the evening, and, when aroused at night by a desire to micturate, to pass water on each occasion into a separate vessel. The greatest quantity obtained at any given micturition represents the maximum capacity of the bladder from a clinical standpoint. Cases in which the frequency of micturition is aggravated at night cannot be gauged in this way and mechanical means must be employed. The chief sources of error here are hyperesthesia of the prostatic urethra and consequent exaltation of the urinary desire, and also too rapid distention of the bladder, producing "surprise" and peremptory muscular reflex in the bladder-wall. The general excitability should be guarded against by sedatives and antispasmodics—a hypodermic of morphine, twenty to thirty minutes before gauging is useful. The local reflexes can be quieted by applications of eucain or cocaine to the prostatic urethra. Whenever, in gauging the bladder capacity, the urine returns at first with some degree of force, but loses this as the test proceeds, it may be safely assumed that temporary distention atony has been produced, and the test will require repetition at another time.

PHYSIOLOGY.

Leucocytosis after Violent Exercise.—The relation between physiological and pathological leucocytosis becomes of increasing interest as our knowledge increases. In order to elucidate to a certain extent this subject Ralph C. Larrabee (Jour. Med. Research, Jan., 1902) has made a study of the leucocytosis occurring in normal men as the result of violent physical exercise. The blood-counts were made within five minutes after the actual finish of a severe foot race of twenty-five miles. In every case a leucocytosis was found varying from 14,400 to 22,200. The differential count showed that the increase was mainly in the polymorphonuclear neutrophiles. The relation between the large and small mononuclear forms was changed, the proportion of large forms being increased. Eosinophiles were both relatively and absolutely diminished. In three or four cases a few myelocytes were found. No abnormalities were noticed in the red corpuscles. Since in this leucocytosis the percentage relations of the various leucocytes is altered from the normal it is certain that it is not physiological in character. More than one factor is concerned in the production of this leucocytosis—probably a temporary mechanical cause, and a toxic cause more slow to develop but lasting as long as the exercise continues.

THERAPEUTIC HINTS.

Muscular Rheumatism.—

℞ Baume de Fioraventi.....c.c. 20.0 (℥v)
Spt. camphoræ.....20.0 (℥v)
Spt. terebinth..... 3.0 (♏xlv)
Chloroformi ..... 5.0 (♏lxxv)
Menthol .....gm. 2.0 (gr. xxx)

Apply with light friction.

—G. Lyon in Le Progrès Médical, Jan. 4, 1902.

Chronic Malaria.—For enlargement of the spleen, rub in twice a day with friction the following ointment:

℞ Iodoformi .....gm. 3.0 (gr. xlv)
Ext. belladon..... 4.0 (℥i)
Ext. belladon ..... 4.0 (℥ij)
Ol. menth. pip.....gtt. xx.

and for the general condition take two of the following pills at noon and two at night before meals:

℞ Ac. arsenosi .....0.001 (gr. 1/60)
Iodoformi .....0.06 (gr. i)
Ferri et potass. tart.....0.06 (gr. i)
Ext. bellad.....0.03 (gr. iss)
Ext. quinquinæ.....0.06 (gr. i)
Quin. sulphat.....0.02 (gr. ⅓)
Ext. nucis. vom.....0.01 (gr. ⅙)
Ext. valerianæ.....0.06 (gr. i)

For one pill.

—M. Stephanopoulos in La Médicine Moderne, Dec. 25, 1901.

Veratrum Viride in Eclampsia.—Three cases of eclampsia in which the convulsions were promptly relieved by hypodermic injections of c.c. 1.3-1.7 (♏xx-xxv.) of the tincture of veratrum viride are described by A. Lapthorn Smith (Montreal Med. Jour., Jan., 1902). In one case half a grain of morphine had been injected, and an enema of a pint of salt solution given every two hours without effect. Vomiting was marked and the pulse excessively rapid, full and strong; following the veratrum the vomiting ceased and the pulse came down to fifty-six and was quite soft. A severe headache persisted, however. In the next case morphine and atropine had been given and a pint of blood removed from the arm, but the convulsions did not subside till an injection of veratrum was administered. In the third case three hundred grains of chloral and half a grain of morphine had been given in the course of four days, but veratrum was followed by very rapid subsidence of blood tension and the complete letting up of the convulsions.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 1, 1902.

FATALITY AND EPIDEMICITY OF PNEUMONIA.

Sometimes even science may benefit by publicity. The series of pneumonia cases at the school at Groton was the main thing in the public eye for some time, because the President's son was one of the patients. These cases call attention to the possible element of contagiousness in pneumonia, so often noted, and it is to be hoped that the publicity given this idea will serve to make it popularly understood that careless contact with pneumonia patients, and especially with the sputum and other discharges, is not without a certain element of danger.

Dr. Lambert, at the recent meeting of the Section on Medicine of the New York Academy of Medicine, stated as his opinion that the concurrence of the series of cases of pneumonia at Groton was no more than a coincidence. The patients all suffered from frank lobar pneumonia of not very severe type. It was just the form of the affection that might be expected to occur in boys with opportunities to exercise freely in the open air during the changeable, yet always rather inclement weather of the last few weeks.

During the discussion on pneumonia at the Section meeting there was general concordance in the opinion that pneumonia may be epidemic and that its contagious character under conditions that involve crowding and close contact under somewhat unhygienic circumstances, as in barracks, jails, old hospital wards, camps and the like, is rather definitely established. Dr. Burt's suggestion as to the exercise of care in the disinfection of the sputum of the patient and conscientious precautions on the part of attendants to prevent dissemination of such material in any possible way may seem to some to push prophylaxis beyond actual knowledge.

There is no doubt, however, that this is the trend of the most conservative modern medical thought. Predisposition and infection may not often coincide in the persons of those in attendance on the patient, but the risk of such coincidence is sufficient completely to justify the ounce of prevention demanded.

Pneumonia, unlike most of the so-called ordinary diseases, is at the present time on the increase rather than the decrease. While the mortality from pulmonary consumption is notably less than it was a decade ago in most cities, the death-rate from pneumonia is alarmingly greater. This increase in the fatality of the disease has come during a period that has seen the general death-rate, in our larger cities especially, very materially reduced. The average length of life has increased in recent years from something over thirty-one years to nearly thirty-six years. Pneumonia continues its ravages, however, not only unimpeded but actually with additional virulence. Three forms of disease, pneumonia, heart disease and pulmonary consumption, are now the chief nursing sisters of death. Heart disease has become more amenable, at least to symptomatic treatment; consumption has been robbed of its worst terror—its presumed incurability; but pneumonia increases in frequency and fatality almost in a direct ratio with the density of population. As the near future is to see our population gathered more and more in crowded urban centers, there is good reason to take every possible precaution to prevent its spread. Many of the precautions now enforced with regard to other diseases would have been considered practically unjustified a quarter of a century or even less ago. Excess of prudence is not a fault to be compared with fatal relaxation of vigilance.

On the other hand, the picture of the present medical status of pneumonia is not entirely unrelieved. The principal reason for the greater frequency of the disease in recent years is the fact that sanitary science has kept alive many more individuals especially susceptible to the dis-

ease than was formerly the case. Weakling infants who perished in the annual visitations of gastro-enteritis in the summer, delicate children who succumbed to the acute infectious fevers in early years, are now preserved to be the victims of typhoid fever and pneumonia in adolescence. Adults who in previous generations did not survive the ravages of acute infections and gastro-intestinal disease in early and middle life, now live on to the fifth and sixth decades and it is on these especially that pneumonia preys. In a word, the prognosis of the disease is not worse in individual cases despite the increased mortality.

The prognosis of pneumonia really depends on what the patient takes into the disease with him. If his heart be already affected the outlook is indeed gloomy. If his kidneys be seriously affected the hope of survival is scarcely more promising. If the arterial system be degenerated by alcoholic excesses it is in the worst possible condition to respond to the sudden strains put upon it by the crises of the disease. Even in young adults the prognosis is not favorable if there has been a marked tendency to anemic conditions during adolescence that shows an unstable equilibrium of the blood and probably indicates a corresponding failure of the vascular system to develop. For such patients there is scarcely need to appeal to the status lymphaticus to appreciate the reason for the inevitable fatal termination, though this condition undoubtedly plays an especially important rôle in adding to the death-rate from pneumonia in the young.

Specific remedies there are none as yet for pneumonia. No form of treatment does more than aid Nature more or less effectively in the conflict with the disease.

If we are to see a reduction of the mortality from the disease, then, it must be by prophylaxis of the conditions that predispose to its development. There seems no good reason to doubt that the pneumococcus is almost universally prevalent in crowded places. When ventilation is insufficient the micro-organism either takes an additional virulence or the resistive vitality is so much lowered as to make the individual susceptible. For pneumonia cases, then, an abundance of fresh air is not only for the benefit of the patient, but also for the protection of those in attendance. It is the duty of physicians to make this clear to the public mind as well as to warn those especially who have once had pneumonia of the dangers of crowded places, theaters, churches, railroad stations, and the like. There seem to be great possibilities for good in these precautionary measures that will lessen the ravages of the worst of our present-day disease-scourges.

RECENT DEVELOPMENTS IN DIABETES.

The more carefully examinations of urine are made the more frequently are unexpected cases of diabetes mellitus discovered. The number of applicants for life insurance refused in this country every year because of the discovery of an unsuspected glycosuria is constantly growing. There was a time less than ten years ago when diabetes mellitus was supposed to be much more rare in this country than in older countries, but recent statistics are dispelling this illusion. Cases were overlooked a few years ago because of faulty methods of diagnosis that now help to swell mortality reports. Diabetes is increasingly interesting as the new century begins, because of the realization of its commoner incidence than hitherto supposed and because of the mystery that continues to shroud its essential pathogenesis in spite of recent advances in nosology. The discussion of diabetes itself at the January meeting of the New York County Branch of the State Medical Association and of diseases of the pancreas at the annual meeting of the Medical Society of the State of New York brought out some points that are distinct additions to our knowledge of the disease.

One of the most interesting questions with regard to diabetes is its possible contagiousness. In many hundreds of cases the disease has been reported as occurring in both husband and wife, and in rarer, though still quite frequent cases, in members of the same household, sometimes even when not related by blood. The well-known family tendency to the disease would, of course, vitiate any claims made on the coincidence of the disease in the cognate. Careful collation of German statistics seemed to show, however, that conjugal diabetes—that is, glycosuria affecting both husband and wife—occurs in less than 2 per cent. of all cases. This minimum of possible communication would seem to preclude all idea of contagiousness. Coincidence and the influence of very similar modes of life would serve to account satisfactorily for perhaps a greater percentage of incidences of the disease in people living together.

Dr. Abraham Mayer reported at the meeting of the New York County Medical Association a series of cases not yet formally published that materially lessens the force of this objection to the theory of possible contagiousness. If the

urine of the supposedly well marital partner be examined as a routine practise in all cases, when diabetes in husband or wife comes under observation it will be found to contain sugar in at least 6 to 8 per cent. of the cases. This proportion is to say the least a complete justification for suspicion of the communicability of the disease and points out the necessity for further careful investigations along this line. We pointed out editorially in the Medical News about a year ago that the *a priori* assumption on general principles that diabetes was not mildly contagious might readily lead to sad results, while the opposite opinion could only be productive of good and would prove a stimulus to investigators.

As was well brought out by Drs. Thayer and Blumer at the recent meeting of the State Medical Society the pathology of diabetes has been very strikingly illuminated by certain American observations during these last few years. Opie at Johns Hopkins has pointed out the significance of degeneration of the islands of Langerhans in the pancreas in diabetes. If these observations are confirmed they will do away with all the difficulties hitherto associated with the problem of the connection between the pancreas and true diabetes. These structures are not connected directly with the glandular canals of the pancreas, but are in intimate relation with a special arrangement of blood-vessels not unlike the vascular supply of the glomeruli of the kidney, or the Malpighian bodies of the spleen. This histological peculiarity stamps the islands of Langerhans as being associated with the internal secretion of the pancreas. Several years ago Prof. Hansemann of Berlin pointed out that even when the pancreas seemed entirely degenerated portions of healthy pancreatic tissue remained. It seems not unlikely that when the secretory gland substance undergoes extensive degeneration beginning in the pericaudicular portions, the outlying parts of the pancreas, distant from the ducts as are the islands of Langerhans, frequently escape destruction. This accounts for the number of cases in which, despite seemingly complete degeneration of the pancreas as a gland, diabetes did not occur. The reason was that the internal secretion had not been interfered with.

On the other hand degeneration of the islands of Langerhans without affection of the rest of the gland has been found by Opie to occur and these are the cases in medical literature in which diabetes has been reported without any lesion of the pancreas. The lesion might easily escape notice because of the comparatively small space occupied by these collections of specialized cells. When neoplasms have caused apparently complete obliteration of the pancreatic tissue it is not unlikely that some of the islands of Langerhans escaped the invasion of the malignant growth or else the malignant cells themselves, though not true glandular cells, supplied the function of the gland cells from which they are separated by but a generation. It has been known that metastatic cancers of the liver deposited in distant tissues produced bile and a corresponding activity is not too much to expect from pancreatic cells similarly degenerated.

Quite recently a rather surprising observation has been made almost simultaneously in Europe and this country with regard to the effect of injections of suprarenal substance in producing glycosuria in animals. Dr. Blum reported in the *Deutsche Archiv für klinische Medicin,* October 30, 1901, a series of successful experiments in this line. Dr. Croftan, working in the Woodward Fellowship for Physiological Chemistry at the Pepper Laboratory of the University of Pennsylvania reports in *American Medicine,* January 18th of the current year, a number of observations of the same kind undertaken when nothing was known of Blum's work. Croftan is inclined to the opinion that the glycosuria observed by him in animals after the injection of suprarenal extract depends on the action of a diastatic ferment in the suprarenal gland which converts the glycogen of the liver into sugar. In the first formal scientific communication made as the result of work done under the auspices of the recently-founded Rockefeller Institute for Medical Research which the Medical News had the privilege of publishing in the issue of February 1, 1902, Drs. Herter and Richards of New York entirely disagree with Croftan's conclusions. As they point out, Takamine's method of preparing adrenalin almost precludes the possibility of an active diastatic ferment remaining in the finished preparation, since the heat employed to get rid of albuminoid substances, an exposure to 90° to 95° C. for an hour, would make the continued existence of such a ferment extremely unlikely. On the other hand, the injections of adrenalin seem to produce changes in the pancreas that stamp the resultant glycosuria as really of pancreatic origin. The changes noted in the pancreas involve especially the cells of the islands of Langerhans, affecting these much more than the acinous gland-cells. This work, then, would seem to con-

firm Opie's observations rather than controvert them and throws light on the pathogenesis of diabetes rather than adds to the mystery as was at first thought.

At the recent meeting of the State Medical Society at Albany Dr. Chittenden of Yale suggested that the effect of suprarenal extract upon the blood-pressure might well be the secret of its causative influence in glycosuria, since it was already known that disturbances of blood-pressure often led to at least a temporary appearance of sugar in the urine. This last striking observation with regard to the suprarenal will doubtless serve to supplement Opie's work and at length solve all the pathogenetic mysteries that have so long been grouped around diabetes. The outlook is certainly most promising and it is a source of no little pride and inspiration that some of the best of this work in diabetes has been and is being accomplished here in America. *Macte virtute!*

"GLASSING" A SIGN OF NATIONAL DEGENERATION.

"Fightin' all day, Sir, and never saw a Boer. Yas, Sir, we simply blazed away at the kopjes on the chance of hittin' a Boer or two." In a trenchant article on recent ophthalmic work in the British Army, Dr. John Grimshaw tells us that this was a very frequent statement from the invalided South African soldiers on being asked whether their eyes had given them trouble when shooting on the veldt. American military surgeons also had occasion to direct careful inquiries into the relation of vision to efficacy in the various departments of the Army and Navy in our recent war with Spain.

Because of the interest shown in these two countries, it can but prove profitable to compare the standards of vision established in Continental Europe with those in force in England and America. For this purpose one cannot do better than turn to an article on "Standard of Vision" by Captain Miles Standish. In the first place the enlisted European conscript is permitted to wear glasses; this, except under quite unusual conditions, is prohibited in England and America.

In the French Army regulations of 1894, which are at present in force, the requirement of vision after correction of myopia is ½ with both eyes together, and not less than $^1/_{10}$ in the poorer eye; in cavalry and artillery, normal vision in one eye and not less than ½ vision in the other.

In Italy the Royal decree of September 26, 1881, rules that reduction of vision to ⅓ the normal in the right eye, or to $^1/_{12}$ in the left eye, although vision in the right eye is up to normal, if caused by organic changes or incurable disorders of the globe of the eye, a very important qualification, incapacitates for military service. The latest Belgian regulations determine that reduction of vision in the right eye to ⅓ of normal causes exemption from service, although reduction of vision below this limit in the left eye does not exempt from duty. The Swiss Army regulations for the minimum of vision for the artillery is normal; for the infantry ⅗, and for all other troops ½. Whenever the vision in one eye is normal, vision in the other may be as low as ⅛; but these conditions do not allow men to be employed as riflemen unless the eye with normal vision is the right eye. The rules in the Danish Army exclude from military service all men having vision below ⅕.

These standards are too low to be brought into relation with those employed in the examination of candidates for the United States Army, which, as would be expected, are by long odds the highest in the world. They are $^{20}/_{20}$ in *each* eye, without glasses. That this standard is unnecessarially high may be judged from the fact that when, upon the outbreak of the late war, large numbers of members of the National Guard were rejected for "physical disability" by the United States examining officers, the natural inference among the laity was that the State troops were mostly cripples and invalids. A $^{20}/_{20}$ vision would theoretically enable the soldier to see a man six feet high at a distance of 1,375 yards, but as a matter of fact, owing to atmospheric and other conditions, a man could not be distinguished at any such distance.

In England it would seem that, while the visual tests are probably grossly tampered with by bribing and other nefarious methods, and while, as is frequently the case, the Englishman has a more or less archaic method of estimating the eyesight, it might be interesting to question whether in the last forty years the national eye, if one may use the term, has become dimmed and whether the lamentable picture of Thomas Atkins shooting at kopjes in lieu of Boers is a result of *this* or of faulty or mismanaged examination. Grimshaw asks why, if the War Office grant artificial teeth to men who are likely to become efficient soldiers, should spectacles be withheld?

There is little doubt that England will soon realize that she must take her place in company with the Continental people and furnish glasses as they do. Obviously this is an admission that

she has in the last half century lost ground physically. It would seem in retrospect that this question of eyesight in the Army affords a tolerable insight; a sort of indicator to the well-being of a nation. Continental Europe has "glassed" a large proportion of her soldiers, this proportion increases from day to day and it is noteworthy that the ratio is highest in the poorest lands. Lord Kitchener's strictures on the physical unfitness of the proud Imperial Yeomanry show that even they, in company with the rest of the British Army, must submit to the wearing of glasses or fail in the race. The yeoman is extinct.

Our own authorities ask for a lowering of the standards. If these premises be true, how long, one can but ask, ere our proud standard must fall, crushed, with many other good things by the onward march of "civilization"? How soon will the "glazing" of our iron regulars proclaim to the world our national decay? When will our $^{20}/_{20}$ standard be borne by that same westward tide to the vigorous New World which, portend says, will one day take life in the dead East?

ECHOES AND NEWS.

NEW YORK.

New Pest Houses.—Commissioner Lederle is planning five new hospitals to serve for smallpox patients, one for each of the boroughs.

Offers $5,000 to Hospital.—Mrs. John H. Burtis, President of the Board of Managers of the Memorial Hospital for Women and Children, Brooklyn, has told the hospital staff that if it will raise $15,000 to meet the immediate debts of the institution and guarantee to pay the remaining debts, which amount, it is said, to $15,000 more, she will give $5,000 additional to the hospital. Mrs. Burtis announces that she is anxious to retire from the head of the institution, and go abroad for a year's rest and recreation. There has been some difference of opinion among the managers of the Memorial Hospital as to the desirability of maintaining the institution exclusively for women.

Nervous Disease Ward.—The Post-Graduate Medical School and Hospital, Second Avenue and Twentieth Street, received last week a gift of $25,000 from Mrs. Hannah N. L. Sherman, of Lawrence, Long Island. This money is to help support a new ward for women and children afflicted with nervous diseases. The ward is to contain fourteen beds, five of which will be supported in perpetuity by Mrs. Sherman's gift. The sum given is not enough in itself to support an entire ward, but makes it possible to devote one entirely to patients suffering from those particular diseases. It will be the only one in the city. The naming of the new ward has been left to Mrs. Sherman, and she has decided to call it the Hope Ward. The five beds will be called the Lawrence beds.

German Medical Society.—At the next meeting of this society on March 3d, Dr. Willy Meyer will read a paper on "What Can be Diagnosed in Acute Appendicitis." Dr. T. W. Bandler will show a case of "Chorioma Uteri, with Microscopical Demonstrations."

Resolutions on the Death of Dr. Munde.—"Death has taken our beloved teacher, friend and helper, Dr. Paul F. Mundé, in the fulness of his fame and power. His universal kindness, his never failing courtesy, his generosity, and, above all, his loyalty, rendered him dear to every member of the Mount Sinai Alumni Association. We shall never forget the lessons learned at his hand, and enforced by his precept. We are better physicians and better men for having lived in close contact with him. In the sorrow that we personally feel we extend to the family our sympathy, most heartfelt and sincere, realizing however that it is impossible 'to gild a grief with words.'"

Committee. { Samuel M. Brickner, M.D., Albert A. Berg, M.D., Charles Goodman, M.D., Martin M. Ware, M.D.

Honor to Dr. Charles Rice.—The movement set on foot by the leaders of the pharmaceutical profession to honor by some fitting memorial the memory of Dr. Charles Rice, late of this city, is well under way and should be liberally responded to by physicians throughout the country. The raising of the standard of the pharmaceutical profession and the present high standard set for the preparations of the Pharmacopœia are largely the results of Dr. Rice's activity.

Research Work at the New York University.—The reports of the laboratories of physiology, chemistry, bacteriology, and pathology, in the Medical School, recently made public, are remarkable as indicating a marked increase in the amount of research work performed. Eight monographs on research subjects have been published from the physiological laboratory during the past year, while the pathological laboratory in the same period has the record of 264 autopsies in gross pathology. Two hundred and sixty specimens were prepared for the Pathological Museum, and 600 specimens illustrating various forms of disease were received from the New York Hospital. The clinical laboratory made 2,532 examinations, of which 1,872 were for classes in the dispensary and 610 for the Bellevue Hospital.

Appointment of Dr. Magill.—Dr. William S. Magill has been appointed research assistant in the laboratory of bacteriology of the University and Bellevue Medical College. Research for the present year in this laboratory will be made in the etiology of smallpox and the chemical products of milk bacteria.

Pneumonia Very Prevalent in New York City.—There has been an unusual increase in the number of deaths from pneumonia and other diseases of the respiratory organs in the last four weeks. During the week ending February 15th, according to the Health Department, there were 334 such deaths, and in the following week, ending February 22d there were 353. In the corresponding week last year there were only 243 such deaths. The increase is said to be due to the epidemic of measles, as cases of that disease frequently develop pneumonia.

Buffalo and the Social Evil.—After a conference between representatives of the Anti-Saloon League, District Attorney Penney and Superintendent Bull of the Police Department in the District Attorney's office of Buffalo, February 22d, the Anti-Saloon League authorized the issuance of a statement in which it conceded that it was impossible to stamp out the social evil and therefore made a compromise. The statement was issued in the name of the Executive Committee of the Anti-Saloon League, consisting of Byron H. Stauffer, O. P. Gifford and John F. Brant, all ministers; District Attorney Penney and Supt. Bull. It was in part as follows: "We realize that the city of Buffalo, during all the years of her history, has, like all centers of population, been compelled to face the problem of the social

evil, together with the various kinds of vice accompanying this evil. We are not desirous of attempting the impossible task of eradicating these evils, for we believe that in attempting this task we would so scatter the vicious element as to aggravate the condition which we have been attempting to ameliorate. We agree that all thoroughfares shall be free from this element, and that it shall be confined to a definite and limited area not traveled by the general public."

Manhattan Dermatological Society.—A regular meeting of this society was held Friday, February 7, 1902, at the residence of Dr. C. A. Kinch, 273 West Seventieth Street, with Dr. W. S. Gottheil in the chair. Dr. J. Sobel presented a case for diagnosis: the patient presented himself at the clinic and a diagnosis of grippe was made; the body showed a morbilliform eruption; the question of rötheln, erythema multiformis, dermatitis medicamentosa, or a dermatitis complicating grippe was considered by the speakers. Drs. Cox and Kinch believed it to be a case of dermatitis medicamentosa. Dr. Bleiman said that the initial symptoms spoke as well for measles as for grippe and the appearance of the eruption favored the diagnosis of measles. Dr. Gottheil could not positively exclude measles; the presence of eruption before medication excluded dermatitis medicamentosa. Dr. Sobel did not regard it as measles owing to the absence of catarrhal symptoms of involvement of face and of Koplik's spots, but strongly suspected grippe with a complicating dermatitis.

Dr. Gottheil presented a case of folliculitis decalvans in a woman about forty years of age. He said that it was unusual for it to attack the scalp alone, and he considered this case as a non-parasitic sycosis. Dr. Sobel spoke of the treatment as it applies to children; Dr. Cox discussed the treatment of adult cases and spoke highly of balsam of Peru. Dr. Abrahams said that acute suppurative folliculitis of the scalp was rare in adults, but common in children. Dr. Bleiman spoke of the similarity of this disease to sycosis barbæ and advised complete epilation and antiparasiticides.

Dr. Gottheil presented a girl of twelve years with two distinct eruptions; one consisted of oval scaly patches upon a hyperemic surface seen on the chest and left iliac region; there was also some scaling on the scalp; this he regarded as a psoriasis; the second was a dark mottled eruption (pigmentation), macular, seen on the back and abdomen, which had been present for two years; the origin was unknown; there was no history of a previous eruption. Dr. Sobel thought the pigmentation of second eruption might be due to maculæ cœrulæ. Dr. Oberndorfer regarded the first as a psoriasis in an unusual location and the second as probably due to arsenical treatment for a previous acute or chronic condition. Drs. Cox, Kinch and Abrahams believed a previous eruption had in the process of healing left this discoloration; the first eruption was regarded as psoriasis.

Dr. Bleiman presented a case for diagnosis: a woman twenty-one years of age, married; eruption present since birth; face is red and hyperemic; the entire body shows scaling to a marked degree; on the feet and lower limbs the epiderm can be peeled off in large patches, leaving a slightly hyperemic base; the skin is thick and dull; patient gave birth to an 8½-months fetus similarly affected; it lived fourteen days. Presented with a probable diagnosis of dermatitis exfoliativa. Drs. Oberndorfer and Abrahams called it a marked case of ichthyosis. Dr. Sobel was not willing to call it dermatitis exfoliativa, but did not classify it as an ichthyosis. Dr. Franklin thought it was dermatitis exfoliativa. Dr. Gottheil spoke against such a diagnosis; he believed it to be ichthyosis. Dr. Bleiman further stated that the history and well-being of the patient did not correspond with the picture of dermatitis exfoliatus, yet he looked upon the case as interesting from a diagnostic point of view. If it was ichthyosis it surely was a very unusual case.

Dr. Abrahams presented a case of mild ichthyosis; the eruption at one time covered the entire body; at present it is seen in patches at various points of the body; the eruption was not observed until after an attack of measles five years ago (boy is now eleven). Dr. Abrahams presented a case of non-congenital ichthyosis, believing measles to be the causative factor. Drs. Cox and Sobel believed all cases to be congenital; the early manifestations are slight and are readily overlooked. Drs. Oberndorfer and Bleiman called it a mild case; in some places it resembles keratosis follicularis. Dr. Gottheil believed both conditions to be present; pathologically both conditions are closely allied; he does not look upon the acute exanthemata as etiological factors.

Dr. Abrahams presented a case of inguinal tertiary bubo (bilaterial). At first the left side was affected, then the right became involved; the buboes attained the size of an orange and were uninfluenced by any teratment until antisyphilitic medication was inaugurated. There was no history of gonorrhea, chancre, or wound; the abdominal and thoracic organs were normal. The patient began to improve only when placed on mercury and the iodides. He regarded this as a rare affection, yet felt tempted to make such a diagnosis owing to its rapid improvement under antisyphilitic treatment, other methods failing. Dr. Gottheil said that unilateral gumma (inguinal) was rare and double gumma extremely so; he considered the source of infection to be the urethra; its response to mercury and the iodides does not necessarily stamp it as specific. Dr. Bleiman mentioned a case of traumatic bubo, in which syphilis was excluded, which got well under antisyphilitic treatment. Dr. Cox agreed with Dr. Abrahams. Dr. Sobel thought that a urethral chancre with secondary symptoms may have been overlooked by the patient and so he considered the bubo as a secondary glandular involvement.

PHILADELPHIA.

University Can Build Veterinary Hospital.—Residents of the locality near Thirty-ninth Street and Woodland Avenue have objected strenuously to the erection of a veterinary hospital by the University in lieu of the old one torn down at Thirty-sixth Street to make room for the new medical laboratories. It was claimed that the act referring to the erection of hospitals in built-up portions of the city applied, but application to the State for an injunction has been refused by the Attorney-General. No reasons for the decision are given.

Typhoid and Smallpox Decreasing.—New cases of typhoid and smallpox for the week ending February 22d were 83 and 63, as compared with 157 and 74 for the preceding week. The greater number of the new cases of smallpox are coming from the northeastern section of the city, where very many of the mill operatives, a large portion being English persons, refuse to be vaccinated. Fourteen cases occurred at the same time in one block among these people.

Changes in Hospital Staffs.—Dr. George E. de Schweinitz, for several years professor of ophthalmology in the Jefferson Medical College, has been elected to succeed the late Dr. Norris as professor of ophthalmology in the University of Pennsylvania. Dr. S. Weir Mitchell, who has been for thirty years associated with the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, has resigned as senior physician,

and will serve only as one of the consultants. In this hospital was begun the first distinct clinic for nervous diseases in this country. Dr. John K. Mitchell has been elected to the vacancy caused by his father's withdrawal. Dr. J. Madison Taylor has also resigned his position as assistant physician of the institution. Dr. D. D. Stewart has resigned as professor of diseases of the stomach and intestines at the Philadelphia Polyclinic, and Dr. Joseph Sailer has been elected as his successor.

Officers of Neurological Society.—Officers of the Philadelphia Neurological Society for the ensuing year are: President, Dr. J. K. Mitchell; Vice-Presidents, Drs. F. X. Dercum and Joseph Sailer; Treasurer, Dr. Guy Hinsdale; Secretary, Dr. A. A. Eshner; Councillors, Drs. D. J. McCarthy, W. G. Spiller and W. C. Pickett.

Address by Dr. Roswell Park.—Dr. Roswell Park of Buffalo delivered an address at the University of Pennsylvania, February 19th, under the auspices of the Charles K. Mills Neurological Society. Dr. Park congratulated the students on the excellent instruction they are receiving, and stated that for that reason he need not confine his remarks to a strictly medical subject. He therefore spoke on "Student Life in the Middle Ages," depicting the manners, customs, and life of the early university students. Their requirements and disadvantages were compared with the present fortunes of students, many incidents illustrative of the life of those times being given. The origin of the customs of dueling, hazing, and fagging were described. After the address a reception to Dr. Park was given at the Roosevelt.

Philadelphia's Water Filtration.—At the meeting of the North Branch of the County Medical Society, held February 20th, Mr. John W. Hill, the engineer in charge of the construction of the Filtration Plant of Philadelphia, read a paper entitled "The Results of a Year's Experimentation with the Filtration of Philadelphia's Water." The author referred to the pecuniary loss resulting to the city from an epidemic of typhoid, and stated that during a year when only a moderate number of cases of this disease were observed the loss would far exceed what it would cost the city to build a filtration plant. Various instances were cited in which the reduction of this disease has exceeded eighty per cent. in the cities which have established filtration plants, since they were put in operation. The various kinds of filters that have been in operation were described and it was stated that the best results have been obtained by first passing the water through a roughing filter, or preliminary filter, constructed of broken stone or slag, varying in size from ¼ to 1½ inches. By this method the final filters can be run at a rate about twice as great, and the expense of cleaning the sand is thus correspondingly reduced. The roughing filters are simply cleaned by flushing, while in the final filters the sand must be taken out, scraped and restored at considerable expense, which is a very great item in favor of the use of the preliminary filter. Numerous tests have been made with different filters by applying waters of different grades of turbidity and containing larger or smaller amounts of bacterial contents, and the reduction in both has almost uniformly been about ninety per cent., in some cases being as high as ninety-seven per cent. Experiments have been made with the waters of both the Delaware and Schuylkill Rivers, the water of the former being the purer. One of the most difficult problems encountered is the removal of the bacillus coli communis. Water containing various amounts of these germs has been tested and, as a rule, there is no evidence of the germ in the filtered water. One difficulty that confronts this work is the fact that during the time when the water in the Delaware River is very low it contains an exceedingly large amount of chlorine, but this is not believed to be sufficient to affect the palatability of the filtrate. Experiments have been made to determine the effect of an elastic mattress covering over the tanks, but this has not seemed to be of any value. One of the principal factors in the successful running of a filter is to keep it at a steady rate. Statistics were given comparing the death-rate of the different cities using filtrated water and those using spring water; in those of the latter class it was shown to be uniformly higher. Dr. James M. Anders opened the discussion and gave an account of the various epidemics of typhoid fever, which have occurred in this and other cities, the majority, if not all, of which he believed could be traced directly to the water-supply. He spoke upon (1) conditions and diseases caused by the use of impure water, and (2) the effect of slow sand filtration as a means of minimizing the prevalence of these diseases. He stated that he believed impure water was responsible for many of the diseases of the alimentary tract, and disturbances of bowels and stomach, in addition to being the direct cause of the outbreak of an epidemic of an infectious disease in many instances; he cited in support of this theory the cholera epidemic of Hamburg in 1892, the epidemic of typhoid in Plymouth, Pa., and various others, many of which, in his opinion, could have been avoided had the cities been supplied with filtrated water.

Dr. D. H. Bergey who has had considerable experience in filtration work, stated that he believed the introduction of filtrated water into Philadelphia would be followed by a very marked decrease in typhoid fever and the kindred diseases. Dr. Samuel Wolfe referred to the fact that the impure water furnished the population of the city at the present time had been the cause of an enormous consumption of various mineral waters and bottled waters, as well as being in his opinion responsible for a certain amount of the alcoholic beverages consumed.

CHICAGO.

Reforms at Dunning.—The County Commissioners are planning many reforms at the county institutions, which include a reorganization and enlargement of the medical staff, relief of the overcrowded condition of the hospital for the insane, and eventually the erection of a series of cottages to replace the present building.

Annual Meeting of the Chicago Eye, Ear, Nose and Throat College.—The faculty held its meeting February 10th. The following were named as Board of Directors for the ensuing year: Drs. William A. Fisher, President; A. G. Whippern, Vice-President; John E. Hoffman, Secretary; Thomas Faith, and H. W. Woodruff.

Alumni Week.—The faculty of the Northwestern University Medical School has set aside the week of June 16th as alumni week. There will be general and special clinics of all kinds, private operations, ward visits, ward walks; men of international reputation will hold clinics at Mercy and Wesley Hospitals, and the alumni will be given special opportunity to see and study cases. It will be a week of concentrated post-graduate work.

Smallpox not Feared.—Having successfully set in motion the agencies for the suppression of smallpox in the territory surrounding Chicago, the Health Commissioner, Dr. Reynolds, refers in this week's bulletin to certain other affections of far more importance as causes of the city's mortality. Scarlet fever, for example, had 924 victims during the last three years in this city, while there have been in the same time only

7 deaths from smallpox. The same is true in regard to influenza and pneumonia, both infectious diseases, and as such legitimate subjects of study. Within the last dozen years influenza has taken a place, if not as one of the principal causes of death in itself, at least as leading to mischievous complications, notably pneumonia, the deaths from which in Chicago have increased more than 50 per cent. since the influenza epidemic which began in the fall of 1889.

Consumption is in Check.—Consumption is being dealt with by a number of agencies and there is little left to learn, but much to do in the practical application of existing knowledge acquired by thousands of investigators. It is substantially in check, if not yet materially diminishing. On the other hand, cancer is increasing with frightful rapidity. In the decade ended in 1870 there were only 7.3 cancer deaths in every 1,000 deaths from all causes in Chicago. In the decade ending in 1900, there were 28.9 such deaths in every 1,000, an increase in thirty years of more than 80 per cent. Last year there were 1,003 deaths from this disease in a total of 24,406 deaths from all causes, a proportion of more than 41 in every 1,000, instead of the 7.3 in the decade of 1870, of the 14.5 in that of 1880, of the 19.8 in that of 1890, and of the 28.9 in that of 1900.

Some Defects of Speech of Peripheral Origin.—Dr. William L. Ballinger read a paper on this subject before a meeting of the Chicago Medical Society, held February 19th. The etiology was presented under the following subdivisions: (1) Nasal conditions which cause defects of speech. The various pathologic lesions were such as produced nasal stenosis and consequent deadness or flatness of tone. The nasal resonance is impaired and the timber of the voice is marred. (2) Nasopharyngeal and faucial conditions, which cause defects of speech. These are chiefly adenoids, hypertrophied tonsils, adhesions of the faucial pillars to the tonsils, paralysis of the palatine muscles, cleft of the soft palate, etc. Here some of the muscles concerned in speech are interfered with, and the speech defect may be more marked than in the nasal conditions. If any of these lesions exist prior to the acquirement of language (say, before the fifth year), there are apt to be serious consequences to the further development of the mental as well as the speaking faculties of the child. Slight impediments to speech at this age are much more serious than the same impediments at a later period of development. The child has difficulty in articulation, of which he is made conscious by those with whom he associates. He becomes sensitive and morbid, seeks seclusion, and the speech centers and the other centers of intelligence lie dormant. He is liable to become an incorrigible or "backward" child. Training and the removal of the lesions causing the impediment will often result in astonishing improvement in speech and mental growth as well. (3) Lingual conditions which cause defect of speech. Adhesions of the faucial pillars to the base of the tongue; congenital shortness of the geniohypoglossus muscle; tongue-tie; hypertrophy of the tongue, etc., were given as etiological factors in defects of speech. (4) Laryngeal conditons which cause defects of speech. It was shown that if the different forms of laryngitis and neoplasms were excluded, there were few defects of speech of laryngeal origin. He referred to a want of coördination between the uplifting muscles of the larynx and the down-pulling muscles as causing a sibilant or falsetto voice. Especial emphasis was laid upon the interdependence of the development of the faculty of speech and the cerebral centers of intelligence. The muscular exercise of the organs of speech seems to have a marked favorable influence upon mental development; hence the great importance of early training and surgical correction of the peripheral lesions of the nose, nasopharynx, fauces, and larynx, diaphragm and chest. Attention given thus early would, in many instances, convert a backward child into one of usefulness and intelligence. (5) The lack of rhythm and control of the respiratory movements of the diaphragm were referred to as causing stammering. This condition is usually associated with a tuberculous condition of the patient, or with a family history of this disease.

Management of the Umbilical Cord.—Dr. C. S. Bacon read a paper on this subject. Nature's plan of removing the cord from the new-born child is by suppuration and inflammation. The method in common use is but little better than the primitive method of Nature. Careful study of the dangers that attend the methods of separating the cord and postmortem examinations of babies dying from two to four weeks after birth show that local inflammation of the navel and infection of the umbilical cord vessels are very common. Contrary to the common view navel cord separation is one of the most serious dangers that menace the new-born. Management of the navel according to surgical principles is possible and should be attempted. The cord may be severed close to the body or from two to three centimeters away from it. When a stump is left, antiseptic treatment is necessary. When amputation is done, asepsis should be striven for. In the first case alcohol is the safest and best antiseptic. It should be applied freely, especially at the junction of the cord and skin, before and after the daily bath. When the cord is tied at the junction of the skin and cord an effort should be made to keep the navel aseptic, therefore no bath should be given. The best plan is to cut the Wharton jelly at the base of the cord and strip it back like a cuff and tie the vessels with fine silk or catgut. Then the navel must be kept perfectly sterile. This can only be done by a physician who has some surgical experience.

Surgery of the Prostate Gland.—Dr. J. B. Murphy read a paper on this subject. The prostate is situated behind the triangular ligament and is in close contact with the rectum. The prostatic urethra occupies its second anterior fifth, being completely surrounded by it. It is possible to remove, therefore, only the lateral and posterior lobes of an enlarged gland and retain the urethra intact. The enlarged prostate, differing anatomically from the normal gland, encapsulates the neck of the bladder and protrudes into its cavity. Around the neck of the bladder, just above the urethra, is the internal sphincter, the tonic contraction of which, with the elasticity of the parts, prevents the escape of urine (Howell). The external sphincter of Henle, in the lower part of the prostate, may, also, aid. The prostate may be completely removed without loss of urinary control. The secretion of the prostate is necessary for fertilization, as it is essential to the motility of the spermatozoa. Practically nothing is known as to the cause of prostatic enlargement. Bangs says it begins before the fiftieth year. It is rare in the negro (Schultz). Benign enlargements of the prostate resemble, histologically, fibromyomata of the uterus. The enlargements may be incapsulated, but usually they are not. The growths may be subcapsular, intramural or submucous; usually they are intramural in the lateral lobes and submucous in the middle.

Indications for Prostatectomy.—(1) Pathologic enlargement, with urinary retention; (2) painful and frequent urination; (3) catheter life; (4) secondary cystitis; (5) pressure on the rectum. Suprapubic prostatecomy was first performed by Dr. Belfield, of Chicago, notwithstanding many statements to the contrary, and he deserves the honor of having first deliberately planned and executed this operation. The suprapubic

is the route which Dr. Murphy followed during ten years' service at the Alexian Brothers' Hospital. In this hospital enucleation or cauterization into the prostate or cauterization of the bladder folds was accomplished through a suprapubic opening. Proust describes a subtotal prostatectomy with subsequent suture of the pedicles. Dr. Guiteras collected 153 prostatectomies by various methods, of which 72.3 per cent. recovered, 11.2 per cent. were failures and 16.4 per cent. died. He concluded that the cures in this operation were better and more permanent than those following prostatotomy, though the mortality was greater than after the Bottini operation. In enucleating the lobes, Dr. Murphy uses sharp hooks after the capsule is opened to draw the prostate into the field and retain it there, and to invert the prostate while it is being detached from the bladder-wall from above downward. The anterior wall or isthmus of the prostate is never removed, as it never presents any material encroachment on the canal. The hemorrhage by the perineal route is much less than by the suprapubic. Up to the present time he has operated on 8 cases by the perineal route, employing the following technic: (1) Semilunar incision from ramus to ramus, convexity forward, down to capsule of prostate. (2) Prostate freed from its attachments to rectum by careful dissection. (3) Incision of capsule and shelling out of enlarged lateral lobe by blunt dissection from behind forward, using the sharp hook retractors to draw the mass out as rapidly as it is loosened from its capsular attachment. (4) Division of gland at junction of lateral lobe with isthmus, thus retaining anterior walls of urethra. (5) Same technic on other lateral lobe. (6) Removal of middle lobe if necessary, with the posterior urethra. (7) Permanent catheter, which is allowed to remain in place from eight to fourteen days. (8) Perineal drainage of bladder through tube, with gauze packing in perineal wound; these to be removed in from three to ten days. The difficulty of prostatectomy is in inverse ratio to its size. All of the eight cases have recovered and all have urinary control. All are relieved of retention symptoms and have dispensed with the catheters.

CANADA.

Hospital Donation.—G. B. Burland, Esq., of Montreal, has offered to be one of ten to subscribe $200,000 for a new building for the Montreal General Hospital of 100 beds.

Death of Dr. R. M. Bucke.—On the night of February 20th, Dr. Richard Maurice Bucke, Superintendent of the London Insane Asylum, accidentally slipped on some ice on the veranda of his residence, instant death resulting. Dr. Bucke was born in 1837 in England and was educated at McGill University where he graduated in medicine in 1862, gold medalist in his class. In 1877 he was appointed Superintendent of the London Asylum, which position he held up to the time of his unfortunate death. He was an eminent alienist and a lifelong friend and literary executor of Walt Whitman. Dr. T. A. McCollum, for twenty years a leading surgeon in the Niagara peninsula, has been appointed his successor.

Hospitals of Ontario Form an Association.—Representatives from the leading hospitals of Ontario met in Toronto during the past week and formed an association. For the past few years the funds of most of the hospitals throughout the Province have been falling off, owing in part to the fact that the Government had cut down the annual grant of 30 cents per patient *per diem*. An effort will be made to get the Government to increase the grant to 25 cents; and steps will also be taken to secure a proper measure of county and civic aid. A further feature of the new organization will be power to conduct provincial examinations for nurses' diplomas. The Association will meet annually in Toronto at the time the local legislature is sitting. Dr. John Ferguson, of the Toronto Western Hospital, was elected secretary and treasurer.

Appointments to the Free Consumptive Hospital at Muskoka.—At the last meeting of the Executive of the National Sanitarium Association, in view of the early opening of the Free Consumption Hospital in Muskoka and the establishment of a third institution near Toronto, the following twenty-five practitioners of Toronto were appointed on the visiting staff of the Association: Drs. W. B. Geikie, H. J. Hamilton, Gilbert Gordon, C. J. O. Hastings, W. T. Stuart, Allen Baines, J. T. Fotheringham, George A. Bingham, C. M. Foster, B. Z. Milner, F. N. G. Starr, William Oldright, T. F. MacMahon, A. McPhedran, W. B. Thistle, R. J. Dwyer, G. A. Peters, Graham Chambers, Andrew Gordon, Charles O'Reilly, D. W. McPherson, R. A. Stevenson, John Caven, A. J. McKenzie, and H. B. Anderson.

Toronto University Medical Building.—The Medical Faculty of Toronto University has decided to adopt the suggestions of the Honorable the Minister of Education with regard to the financing of the proposed new medical building. The Trustees of the University will advance the necessary $125,000 and the Medical Faculty will pay four per cent. annually on that sum. This arrangement will render any assistance from the Ontario Government unnecessary and will leave the Medical Faculty free to rent a portion of the building to the Arts Faculty or not as they see fit. It is understood that the proposition will be sanctioned by the Government.

McGill University.—The number of students in attendance at lectures this session in all the faculties reaches 1,114, as follows: Law, 60; medicine, 490; applied science, 254; arts, 294; veterinary science, 16. The University has been the recipient of large gfts during the past year. Those particularly concerning the Medical Faculty are as follows: By Sir William Macdonald, $60,000 to endow the chair of chemistry; $50,000 to endow the chair of botany; $20,000 to supplement the endowment of the chairs of physics bearing his name; $30,000 for storage batteries; the new medical buildings donated by the Honorable Mrs. Howard and Lady Strathcona. The revenue of the University during the past year inclusive of cash on hand, amounted to $393,552.90 and the expenditures, $341,756.97.

Annual Meeting Montreal General Hospital.—The annual meeting of the Governors of the Western Hospital, Montreal, was held during the past week. The retiring officers and staff were all reëlected. The only election was that for the position of assistant laryngologist, Dr. George K. Grimmer being the successful candidate. Dr. F. G. Finley, the Secretary, read the annual report. It stated that the ordinary income for the eight months ending December 31, 1901, was $50,183, and the expenditures $60,287. The medical report showed that the number of patients treated in the same time to a conclusion was 1,919. Of these 154 remained over from the previous year; 168 remained in the hospital at the end of 1901, and 1,933 new patients were admitted. There were discharged during the year 2,573 patients, and there died in the hospital 148. The death rate was 7.7 per cent. as compared with 8.5 for the preceding year. The average cost per patient *per diem* was $1.43. In the outdoor department there were 20,189 consultations.

GENERAL.

Phenacetin Patent Upheld.—On February 5th was brought to a termination an interesting case involving

the patent rights to manufacture phenacetin that has been in the courts for over ten years. The original importers, the Farbenfabriken of Elberfeld, have won the suit.

Retirement of Dr. Kinyoun.—Dr. J. J. Kinyoun, for the past year commanding officer and chief surgeon of the United States Marine Hospital at Detroit, and one of the ablest bacteriologists and most valued plague experts in the United States government service, has just sent in his resignation to the Surgeon-General at Washington, to go into effect May 1st. Dr. Kinyoun has been in the United States Hospital Service for about fifteen years, and during that time has been sent all over the world for the purpose of germ study. Dr. E. K. Sprague has been appointed to succeed Dr. Kinyoun as surgeon in charge of the Marine Hospital, and Dr. Herbert J. Higgs has resumed duties at the post-office branch.

Medical Society of City Hospital Alumni of St. Louis.—At the last regular meeting, held February 20, 1902, Dr. H. L. Nietert read a paper on "Penetrating Stab-Wound of the Heart, with Presentation of Patient." Dr. Frank Winter read a paper, entitled "Some Observations of Gunshot Wounds in the Philippine Islands." Dr. G. Hurd, through the Secretary, presented a paper on "Life."

St. Louis Medical Society of Missouri.—At the last regular meeting of this Society, held February 22d, Dr. C. H. Hughes read a paper on "The Neuropathological Aspects and Neurotherapy of Marasmus Infantilis."

In view of the existing epidemic of smallpox, and the general interest manifested therein, the evening of Saturday, March 1st, will be devoted to the consideration of this subject. Dr. W. T. Corlett, of Cleveland, and Dr. A. W. Brayton, of Indianapolis will take part in the discussion.

Gregory Testimonial Banquet in St. Louis.—The date of the testimonial banquet to Dr. Gregory has been set for Thursday evening, April 17th. A committee on invitations has been appointed which is certainly unique in that it is composed of one member of every class taught by Dr. Gregory, 50 in all. The banquet will be held at the Planters' Hotel and will doubtless be one of the largest and most impressive affairs of the kind ever held.

Harvard Medical School.—According to a statement issued February 20th by Dr. Warren and Dr. Bowditch of the Harvard Faculty, but $294,000 remains to be raised out of the sum stipulated by John D. Rockefeller as necessary before his gift of $1,000,000 towards the endowment of the Harvard Medical School would go into effect. At the time Mr. Rockefeller made his conditional gift to the University, $765,000 in addition was needed to complete the amount required to carry out all the plans of the University in connection with the Medical School. Mr. J. Pierpont Morgan is one of those who have contributed largely to the school, having agreed to give $1,000,000 without conditions.

Obituary.—Dr. Levi Cooper Lane is dead in San Francisco. He was a surgeon and founder of the Cooper Medical College and the Lane Hospital..

Dr. Louis Lewis, of Philadelphia, died in St. Vincent's Hospital, New York, February 20th, after an operation. He was born in England sixty-three years ago and came to this country in 1883, settling in Philadelphia. He was a graduate of the Royal College of Surgeons, and of the University of London. He was also a fellow in the Surgeons' Society of the Royal College of Surgeons, and a member of the British Chemical Association. Dr. Lewis served for a short time as surgeon in the British army. He was editor of the "Medical World," the "Medical Council," and the "Medical Times and Register."

Dr. Edward K. Bacon, one of the most esteemed of the younger members of the Detroit medical profession, died last week at his home. His death resulted from pneumonia. Dr. Bacon was born in Ypsilanti, Mich., where he received his early education. He matriculated in the Michigan Medical College of Medicine with high years and attained prominence among his colleagues. honors. He had practised in Detroit for the last seven His widow survives him.

French.

CAUTERIZATION OF THE EYE INSTEAD OF ENUCLEATION—THE INFLUENCE OF HEREDITY AND DEGENERACY IN OBSTETRICS—APPENDICITIS AND GENERAL INFECTION—EARLY DIAGNOSIS OF TYPHOID FEVER—THE ANTERIOR COMMISSURE OF THE SPINAL CORD—HORSE SERUM AND INFECTION—THE FORMATION OF RED BLOOD-CELLS—GELATIN AND THE BLOOD—HIGH FREQUENCY CURRENTS AND THEIR DIRECT APPLICATION TO ANIMALS—THE FORMATION OF THE EYE—PHLEBITIS OF THE SUPERIOR MESENTERIC VEIN—GENERAL TELANGIECTASIS AND CASTRATION.

Many valuable papers were read before the French Societies at the close of the year. The chief are the following:

Vallin, at the Academy of Medicine, December 31, 1901, presented in the name of Panas and of Dianoux a communication on a new method of operating on the eye, with the following chief points: Enucleation of the eyeball, especially in children, is a deplorable intervention because of the deformity which results from it and which, as age advances, tends to grow greater. With the exception of malignant tumors and traumatic infectious inflammation of the eyeball, it would be better to employ the method described by these authors. The following is the technic. Upon the cornea, without opening the anterior chamber, a ring, perhaps two millimeters in diameter, is made with the cautery at dull red heart. After this has been completed the disk so marked out is scooped away and the cornea is perforated at the center by rapidly increasing the heat of the instrument. Thus the contents of the anterior chamber are evacuated. The wound is then sprinkled with bismuth powder and the eye is kept protected by a compression bandage for three days. At the end of this time the surface of the wound is washed with hot water and between the lids a few drops of cocaine and eserine in the form of a collyrium are used. This treatment is continued until the wound is entirely healed. After this is an accomplished fact and all irritation is gone, the final result of the operation is brought about by massage.

Larger reported two cases showing the influence of heredity and degeneracy in the field of obstetrics. The first was that of a young woman who had had one normal childbirth, but during the second was seized with numerous manifestations of hysteria. The child born at this time presented many of the same characteristics. In the second case the mother had had three perfectly normal deliveries, and during the siege of Paris had become again pregnant. The boy brought into the world at this time presented by the face with prolapse of one arm and showed several signs of degeneracy. These cases and similar ones reported by other authors seem to show, according to Larger, the mechanical theories really admitted in obstetrics and

to disprove notably the inaccuracy of the law called the law of Pajot, or the law of accommodation.

Simonin, at the Medical Society of the Hospitals, December 27, 1901, presented a series of eighteen cases of general infections, severe scarlet fever, erysipelas, mumps, and infectious angina, in which were observed positive signs of inflammation of the appendix. According to the author this organ may be considered as a kind of tubular ganglion, which takes part during the course of general infection in the defense of the economy and receives the germs by the circulation of the blood as well as of the lymph. The first degree of inflammation of this organ, which might be called appendical folliculitis or adenitis, is shown by pain at the point of McBurney. This is also called latent catarrhal appendicitis. The second grade presents a peri-adenitis, that is to say, an inflammation of the cellular tissue around the appendix. The inflammatory reaction may propagate this as far as the mucosa and the peritoneum. Then follows a crisis or a colic of the appendix more or less acute, with distinct pain, nausea, vomiting and signs of peritonitis. Finally, an appendicitis with abscess may develop after perforation has occurred. The streptococcus is certainly the most frequent agent. Most of these appendicites arise from this germ. It is this same germ which is present ordinarily in angina, erysipelas, scarlatina, grip, measles, smallpox, and it may be the initial agent of infection or associated with some other. Certain authors consider sclerosis of the appendix with obstruction, which one sees so often at autopsies, the result of several attacks of inflammation, latent, subacute or acute, which have occurred during infectious diseases. Such infectious diseases commonly occur during childhood. This is a clinical fact which appears to substantiate the above theory.

J. Gourmont read a paper on the early diagnosis of typhoid fever by finding the bacillus of this disease in the blood. He states that its presence is constant in those ill with this disease, whether it be of mild or severe degree. The bacillus appears in the blood usually very early, about the fifth day, and continues to be present up to the seventh week. In the prolonged cases with relapses it may be found at a still later period, but this fact is not by any means constant. The germs found in the blood in this observation present all the classic characters of the bacillus of Eberth, excepting that there is very little tendency to agglutinate. The presence of the bacillus of typhoid fever in patients with the disease has no relation with the serum reaction. This may be very slight and yet the germ be present in the blood as early as the fifth day. This fact seems to present a means of dagnosing the disease very early when the reaction of Widal is uncertain or absent.

R. Petit read a paper on the utility of blood-serum from the horse for preventing infection of wounds. His foundation is both experimental and clinical and indicates that the serum of the horse heated to 55° C. exercises a stimulating action on the phagocytes, advantage of which can be taken to prevent infection in wounds and to hasten their healing. The serum has been used in three cases of laparotomy in man. He employs a dose of ten cubic centimeters which he injects into the peritoneal cavity after the operation is over.

Lombard at the Academy of Medicine, January 7, 1902, presented in the name of Laffont and himself a communication in which they stated that glycosuria, albuminuria, and hemophilia have for their cause a variation in the cryoscopic property of the blood. This variation is accompanied as a rule by changes in the liver, in the kidneys, and in the small blood-vessels. All these may disappear, according to these authors, if the normal consistence of the blood is produced. The means which appear to him the most active for obtaining this result consist in the administration by mouth of gelatin in water, fifteen grams a day as the total.

H. Bordier and Lecomte, at the Academy of Sciences, December 30, 1901, discussed in a paper the action of high frequency currents when applied directly to animals. When such currents are applied directly to man they are usually not accompanied by any sensation, which fact may be explained by assuming that these currents simply pass over the surface of the body without penetrating the deep tissues. Experiments enabled them to confirm this hypothesis. By applying the current directly to animals, rabbits, guinea-pigs and rats, they were able to kill them. If two collars were used, one around the neck and the second around the body, death came a few days after signs of paralysis appeared. If one pole was placed in the animal's mouth and the other in the rectum death occurred in the rabbit in five minutes, in the guinea-pig in seven minutes, and in the rat in forty seconds.

Picque, at the Society of Surgery, January 8, 1902, said that Gregoire and himself had had occasion to observe two cases of phlebitis with thrombosis in the superior mesenteric vein followed by gangrene of intestine. This is a rare affection. So far as is known only twelve other cases have been reported. The first case was that of a patient who, after twenty days of diarrhea and three days of constipation, suffered from hemorrhages from the bowel. An exploratory operation was done at which no positive diagnosis was made. The man died and at the autopsy a phlebitis with thrombosis of the superior mesenteric vein and extensive gangrene of the intestine were found. The second patient was admitted under the diagnosis of volvulus of the intestine. At the laparotomy it was possible to make out large areas of gangrene in the intestine, without, however, the least degree of volvulus. At the autopsy he found a condition of affairs similar to that which existed in the other case. Quénu in discussing this paper said he felt that the authors were wrong in part of their contention, namely, as to the priority of the lesions. They claimed that the disease of the vein preceded that of the intestines, whereas in his opinion it was probable that the thrombosis and phlebitis of the vein were due to the invasion of it by some bacteria which had previously been the cause of the diarrhea, constipation and bleeding. These were certainly cases in which the absence of a bacteriological examination was to be regretted.

TETANUS AND CARBOLIC ACID.

To the Editor of the Medical News:

Dear Sir: The following patient with tetanus was treated by repeated subcutaneous injections of a one-half-per-cent. watery solution of carbolic acid and recovered.

A girl, aged thirteen years, presented herself for treatment at my office last July with the following history: Seven days previous while playing in a barnyard she had fallen upon a barbed wire fence, severely lacerating her right hand. Physical examination revealed only three points of interest, viz., a cicatrix at the seat of the injury (palmar surface of the right hand), a slight stiffening of the masseter muscles, and a spasm of the flexor group of the right forearm. The child complained of difficult deglutition and of slight drowsiness.

Considering the nature of the injury it was thought best to freely incise the parts. This was done and the

wound thoroughly irrigated with a solution of hydrogen peroxide three per cent. and lightly packed. On the following day the patient presented clearly-defined symptoms of tetanus. There were generalized spasmodic contractions. The skin was hypersensitive and the reflexes were greatly increased. The jaws were nearly set and the eyes were very sensitive to light. The right hand was markedly flexed. Deglutition was difficult. Micturition and defecation were normal. The temperature was normal and the mind clear.

The child was put to bed in a dark room, kept quiet, given a laxative and a dose of bromide. The wound was irrigated with a three-per-cent. solution of H_2O_2, and a number of hypodermatic injections of a one-half-per-cent. watery solution of carbolic acid were then made in a circle around the wound. In all thirty minims were injected.

The next day the symptoms were more intense. The treatment continued the same; the injections were made more frequently, however, thirty minims being injected every three hours.

On July 25th the child showed signs of improvement. The jaw muscles were somewhat relaxed and the right hand could be extended by passive motion. On the following day there were signs of systemic poisoning from carbolic acid. The injections were therefore reduced in frequency to one *per diem*. On the 27th the spasms were aggravated, the jaws were more tightly set and the right forearm and hand rigidly flexed. The injections were again administered more frequently, three times a day. These were followed by a gradual relaxation of the muscles, and from July 27th until the middle of August there was improvement until August 19th, when the child was able to walk to my office. The injections were gradually diminished until but one was given every second day. The bromides were administered daily.

Kenneth E. Kellogg.

SOCIETY PROCEEDINGS.

NEW YORK STATE MEDICAL ASSOCIATION—NEW YORK COUNTY BRANCH.

Stated Meeting, Held January 20, 1902.

The President, Parker Syms, M.D., in the Chair.

Primary Sarcoma of Pancreas.—Dr. Edward Schnaper presented specimens from two cases of primary sarcoma of the pancreas. This pathological condition is extremely rare, very few being reported in medical literature. In one of the cases no diabetes and no tendency to glycosuria had been found, though for months most of the pancreatic tissue had been infiltrated by the sarcomatous neoplasm.

Symposium on Diabetes.

The principal scientific business of the evening consisted of a series of papers on diabetes, the first of which, on the etiology and pathology of diabetes, was read by Dr. Charles F. Nammack.

Alimentary Glycosuria.—Dr. Nammack said that alimentary glycosuria is probably much more common than is usually thought. Small amounts of sugar in the urine should be looked for very carefully. A number of drugs produce glycosuria—Ether, when taken by inhalation, amyl nitrite, mercury, hydrocyanic acid, sulphuric acid, alcohol, strychnine, glycerin and nitrobenzol; alcohol is an especially frequent cause of glycosuria. The combination of chronic gastritis, chronic alcoholism and chronic hepatitis, furnishes the largest number of cases of non-diabetic glycosuria. Traumatic glycosuria is met with particularly in injuries of the nervous system. Portal thrombosis, acute yellow atrophy of the liver, and perhaps phosphorus-poisoning will also set up glycosuria. Most of these cases can be distinguished, however, from true diabetes mellitus without difficulty.

Composite Diabetes.—Dr. F. W. Pavy differentiates two classes of diabetes—alimentary and composite. In composite diabetes there is not only defective carbohydrate assimilation, but also abnormal tissue disintegration and the presence of degradation products. These products appear in the urine as beta-oxybutyric acid, diacetic acid and acetone, indicated by the appearance of a red wine color on the addition of ferric chloride. True diabetes mellitus is increasing in New York. This is probably due to the more strenuous life of the present generation; the bustle of present-day existence is hurrying one on to premature decay of tissue. Of 202 deaths from diabetes in New York (Manhattan and The Bronx only) in 1899, 51 were in patients of Irish extraction, 54 among Jews. One compiler of statistics claims that this greater incidence of diabetes among these two classes of people is due to persistent breeding in and in. To Dr. Nammack it seems that this special frequency of diabetes is due rather to the struggling earnestness of both people; heredity does play an important rôle, however. Those occupations furnish most diabetes which involve continued and excessive mental application. The excessive use of tobacco may have a like result. Emotional stresses when intense or protracted also have a marked influence. The association of insanity with diabetes is so marked as to be more than a mere coincidence. The connection between gout and glycosuria is so intimate that they may be almost considered as convertible conditions, the symptoms of one often distinctly alternating with those of the other. Obesity and diabetes also have close relations; usually this lipogenous diabetes, or diabetogenous obesity yields to treatment, but later on the composite form of diabetes may develop.

The Pancreas and Diabetes.—There is some close relation between certain cases of diabetes and lesions of the pancreas; somehow, however, extensive lesions of the pancreas may occur without diabetes and sometimes diabetic patients have normal pancreases. It is not the loss of the pancreatic juice which produces diabetes; the diversion of this through a fistula is possible without glycosuria. The theory is that there is an internal secretion from the pancreas which has a glycolytic property. Changes in the liver have also been noted in diabetes, but the pathogenesis of the disease is not understood.

Suppuration in Diabetes.—Dr. Arpad Gerster, in discussing the surgical aspects of diabetes, said that it is probable that the reason for the frequent growth of pyogenic micro-organisms, especially the staphylococcus and streptococcus in the tissues of diabetics, was due to the fact that these micro-organisms grow better on a sugared medium. Especially is this true if about the percentage of sugar is added to the medium that occurs in diabetic blood. This was demonstrated by Fritz Grossman, who also showed that if, in rabbits, glycosuria is produced by means of nitrite of amyl, it is very easy to cause gangrene and various suppurative processes in the animal tissues.

Insidiousness of Diabetes.—Dr. Gerster said that diabetes is an extremely insidious disease; in the beginning of its course, glycosuria is nearly always intermittent. Urinary examination may prove negative and yet diabetes may be present. Usually in these cases, however, careful taking of the history will elicit the fact that polyuria and thirst are sometimes present and

also some of the other symptoms of diabetes. At times the sugar in the urine disappears during the drain of suppuration upon the system; on the other hand, infectious fevers nearly always stop the glycosuria because of the retrenchment of the diet that occurs as the result of loss of appetite. Dr. Van Noorden said that in seven cases of diabetes that occurred in doctors and pharmacists whose urine had been frequently under examination, without any suspicion of the disease, sugar was found to be intermittently present for a long time before the diabetes absolutely established itself. There is a popular belief that certain peoples' tissues heal easily, while those of others do not heal except after suppuration; it is not improbable that these latter are suffering from latent diabetes. In the old times it was the custom to make a test incision when a grave operation was contemplated, and if this incision through the skin did not heal kindly, the more serious operation was not performed. The possibilities of latency make it clear how necessary it is to examine carefully the urine of all patients who are about to be submitted to a surgical operation.

Frequent Surgical Complications.—The most common surgical complications of diabetes are furunculosis and carbuncle; few diabetics escape these. Carbuncles may, however, occur without a diabetic basis; in fact, in German statistics, of 32 cases of carbuncle, only two patients had sugar in the urine. It is easy to understand how the polyuria, so frequent an accompaniment of diabetes, may cause a dry skin that becomes very easily irritated; the scratching incident to this condition leads to inoculation with pyogenic micro-organisms and hence the furuncles.

Sugar in Sweat.—At times furuncles occur in diabetic patients who sweat very freely. In these cases, however, it will usually be found that there is sugar in the sweat, the presence of which easily leads to irritative conditions. The phimosis which is so common a complication of diabetes is due to the presence of irritating sugar in the urine.

Location and Size of Carbuncles.—The typical place for carbuncles is on the dorsum; they may occur in any locality from the occiput down to the sacrum, but occur most frequently on the face. At times they may reach a very large size. Dr. Gerster has seen one which reached from the occiput to the lumbar region. Diabetic carbuncle of the face must be treated surgically as early as possible, otherwise thrombosis of the emissary veins may lead to intercranial infection; and so to a fatal termination.

Diabetic Gangrene.—The most common form of gangrene is that of the skin and it affects especially the legs. It may begin as a small blister, due to friction, to the application of a vesicant or mustard plaster, to the prick of a hypodermic needle, or to the irritation produced by a truss. It should be treated by the application of moist dressings wet with mild antiseptics. If infection of the gangrenous area takes place extensive ulceration follows and phagedena may set in. The perforated ulcer of diabetics is not different from that of other patients. The gangrene of a whole extremity is not a very unusual occurrence in diabetics. It occurs seven times more frequently in the leg than in the arm. The previous history of the patient usually shows that there has been the intermittent lameness described by Charcot. Attacks of this affection begin with a painful numbness and fatigue of the extremity, while the toes become slightly blue, showing that there is interference with the vasomotors. If in these cases sugar is found in the urine, the occurrence of gangrene sooner or later may be predicted. Gangrene occurs four times more frequently in men than in women. The reason for this is probably that men have more exhausting occupations and so greater degeneration of their arteries than women. At times amputation becomes necessary in diabetic gangrene; about one-half the patients die, many from diabetic coma. In the preantiseptic days, Landouzy said that diabetic gangrene was a *noli me tangere* for surgeons. Jonathan Hutchison counseled high amputation even if only the toes were involved in the gangrene. A middle position between these two opinions is now occupied. The conservative method gives very satisfactory results. The leg is raised and kept perfectly dry, no poultices or moist dressings are used, and the formation of the line of demarcation is waited for; the affected part is allowed to drop off, but no cutting is done unless absolutely unavoidable. If amputation become necessary the point may be selected according to the condition of the limb. If the pulse is good in the popliteal space, amputation may be performed below the knee; if there is any doubt of the pulse here, then go higher. Infection from the gangrenous area must be carefully avoided, so that the amputation should be done at some distance away. The decision is often for high amputation. Dangers of operation are, first, the anesthetic, feared because of the cardiac debility; secondly, the coma, which often follows major operations in diabetic patients. Coma is due to the presence of acid substances in the blood, these being due to a too restricted diet and to the absorption of tissue products during and after the operation. Very restricted diet must be avoided before the operation and the strictest antisepsis and asepsis secured during the operation. The operation should be performed in the morning when the patient is reasonably fresh and not in the afternoon when he is tired and played out from the day's fast. The amount of starch and sugar in the dietary just before and after the operation should be increased even though this increases the glycosuria. Before and after the operation two grams of bicarbonate of soda should be injected, in order to lessen the acidity of the blood. Chloroform and ether have equal dangers. Diabetic coma has occurred after local anesthesia by means of cocaine in an operation for cataract. Its use probably does not lessen the danger. The Esmarch bandage should be avoided and the arteries should be compressed digitally in order to avoid all injuries of the tissues that might lead to a recurrence of the gangrene, long flaps should be avoided and sutures not employed as they favor necrosis of tissue, but short flaps should be made and the wound left open to heal by granulation. Every case of surgical intervention should be preceded by careful examination of the urine of the patient; if there is any doubt of the presence of sugar a test-meal of eight ounces of bread and sweets should be given, when, if glycosuria does not follow, there is no diabetes. The prognosis of surgical operations in diabetes does not depend on the amount of sugar in the urine, even when patients have as high as six per cent. of sugar, the majority of them recover from surgical intervention. The important factor is the acidity of the blood, which induces coma. It is this that shows the decadence of the tissues. The absence of the knee reflexes is said to be a sign of a bad prognosis. In the last ten years thirteen cases of major operations in diabetic patients have occurred at Mt. Sinai Hospital. Five of the patients operated upon died of coma in from three hours to three or four days, directly following the operation. Two other patients died five to six months later. These, of course, have no connection with the operation. As a rule at Mt. Sinai, cutting operations are done only when absolutely necessary; if, for instance, a toe becomes gangrenous and the bones should project beyond the sloughing tissues, the periosteum is pushed

back and the bone is enucleated at the next joint. The expectant treatment is carried out to the fullest extent possible.

Diabetic Affections of the Eyes.—Dr. S. Busby Allen said that every tissue of the eye may be affected by diabetes. It is not surprising to find that the fundus of the eye should suffer in so serious a disturbance of metabolism. When the ophthalmologist looks at the eye-grounds he is really gazing at brain tissue. This is extremely delicate and easily affected. Both internal and external ophthalmoplegia may occur in consequence of complications of diabetes. The occurrence of muscular eye weakness in a patient of thirty-five must always arouse suspicion of diabetes. Even in comparatively early years diabetes may produce changes in the shape of the eyeball or the lens so as seriously to disturb vision. Such changes have been reported in patients under forty. They must be guarded against because the proper treatment of diabetes will lessen the tendency to their occurrence.

Diabetic Cataract.—This is the most characteristic eye lesion produced by diabetes. It is all the more interesting because other serious metabolic diseases do not cause its development. Noyes has said that changes in the lens are not due to inflammation, but are really degenerative in character. It is extremely interesting to consider what poison it is that produces cataractous changes. There is really no difference discoverable between diabetic and ordinary senile cataract. In old patients one cannot be sure whether cataract is due to diabetes or merely to senescence except after careful examination of the urine. In very young people, of course, the occurrence of double cataract or of very rapidly progressive cataract is almost a sure index of diabetes. Recent studies have shown us that amblyopia is especially liable to occur as a consequence of the use of tobacco. It may, however, occur in diabetic patients in the absence of either alcohol or tobacco. It is a true toxic amblyopia, due very probably to the presence of poisonous acids in the blood.

Eye Operations in Diabetes.—As far as possible operations upon the eye in diabetic patients should be done during lulls in the disease; that is, at times when the amount of sugar in the urine is less than usual. Operations for cataract are usually followed by iritis, but this is commonly not serious. It must be remembered that cyclitis in diabetic patients may easily lead to glaucoma, or may interfere with the nutrition of the vitreous or of the cornea. Even slight injuries of the eye should be cared for scrupulously in diabetic patients or they may have very serious consequences. Simple ulcer of the cornea in diabetes, as in nephritis, may readily lead to the loss of an eye.

Prognosis of Diabetes.—Dr. Abraham Mayer said that the prognosis of diabetes depends on a number of factors. The age of the patient is especially important; the younger the patient, the worse the prognosis. The presence of arteriosclerosis in a comparatively young patient with diabetes adds to its seriousness. Traumatic or syphilitic diabetes is of more favorable prognosis than other forms. Old patients in whom the disease has already lasted for a long period are not liable to be seriously inconvenienced by diabetes or to have their lives shortened. The coexistence of obesity is a favorable factor. The so-called uric-acid diathesis is also a favorable condition. Much depends on whether the patient is in such circumstances in life as to make proper diet and hygiene possible. The existence of phthisis in a case is always serious. The presence of nephritis makes the prognosis very grave. Serious organic disease of the pancreas is an index of early fatal termination as a rule. The patient's general condition, the state of the heart and of the digestive tract are also important factors in prognosis. Diabetes may be divided into mild, medium, severe, and very severe forms of this disease and in the first two classes the prognosis is reasonably good as regards life. The standard as to the form of diabetes present in any case is the test whether a patient after a rigid diet is free from glycosuria. If no sugar occurs in the urine, then the case is mild. If, in order to remove the sugar from the urine nitrogenous products in the diet must also be limited, then it is a mediumly severe form of the disease. The severe diabetes gives glycosuria even when no carbohydrates are present in the diet.

Treatment of Diabetes.—The principle upon which the hopeful treatment of diabetes is founded is enunciated by Naunyn. When any weakened function is rested it gets better and stronger, abuse of weakened function on the contrary leads to its further deterioration. A lessened amount of sugar in the dietary, by sparing the metabolic function for sugar increases its power. Hence the dietetics of diabetes become really curative in effect.

Dietary.—The quantity that a diabetic patient may take must be regulated as well as the quality. Many of these patients suffer from overfeeding. Fats and albumin must be the main portion of the food. They suffer most for want of bread. Dr. Mayer has found that walnuts may replace bread. They are taken with evident relish. When there is a tendency to emaciation an abundance of fat must be given. Alcohol aids in the digestion of fats and besides replaces a certain amount of food material by the heat it supplies when burned up in the system. It thus reduces the tendency to phthisis and coma.

Drug Treatment.—Any number of drugs have been recommended, but most of them fortunately have fallen into disuse. Opium remains the most effective drug for the disease. It not only lessens the thirst and hunger and so reduces the sugar, but it also improves the assimilation, allays the nervousness, irritability and tendency to itching. A half grain three times a day may be given at the beginning; cascara should be administered to prevent constipation. Dr. Mayer has found various salts of arsenic very useful but he has not found that combinations of gold and arsenic are better than others. A most effective drug in Dr. Mayer's hands has been the sublimate of mercury. This is given in doses of one-sixteenth of a grain, three times day, in a large glass of water; it is not suitable for every case, but in diabetics of sluggish bowels in whom the bacterial cause seems prominent and the absorption of intestinal toxins an etiological factor, this remedy exerts a very favorable influence.

Insidious Glycosuria.—Dr. Bierwith said in the discussion that it is not an unusual thing to find glycosuria without increase of the quantity of urine passed, or increase in the specific gravity of the urine. In these cases surgical procedures might easily be determined upon without realization of the patient's condition, though, needless to say, they involve serious risks. Treatment of diabetes in order to be successful, must begin early, and for this early discovery of the glycosuria is important. Diabetes as seen in different patients is not always the same disease, but has a different pathological basis and a different etiology in many cases. Dr. Bierwith is not sanguine as to the successful treatment of diabetes.

Suprarenal in Diabetes.—Dr. James J. Walsh called attention to the fact that in recent experiments a direct connection between the secretion of the suprarenal glands and the occurrence of glycosuria seemed to have been found. These experiments are the most interesting recent observations in the patho-

genesis of diabetes. They serve to show how incomplete knowledge of the subject is as yet. With regard to latent diabetes the glycosuria will be discovered if certain suspicious signs are borne in mind. Loss of muscular power, for instance, soreness of the gums, loss of sexual potency, lapses of memory, greater disinclination than usual to work in young subjects, are apt to be the earliest symptoms of diabetes and should arouse suspicion. With regard to the prognosis of the disease the tradition in Germany is that no patient has lived more than two years after the Gerhardt reaction was found positive in the urine.

Possible Contagiousness.—Dr. Walsh said that the occurrence of diabetes in husband and wife is now known to be comparatively so frequent that the possible contagiousness of the disease is a practical point to be borne in mind. It may be that some ferment which finds its way into the circulation is responsible for the splitting of the sugar molecule that renders it unsuitable for nutrition; such a ferment might easily be communicated.

In closing the discussion, Dr. Mayer said that while only one per cent. of the cases of diabetes in thus far published reports occurred in husband and wife, in statistics gathered by himself in which he always asked for a sample of the husband or wife's urine, when the other was affected, he found glycosuria in five to eight per cent. of the cases. He believes diabetes to be contagious and infectious. With regard to the use of bichloride of mercury, European authorities consider that it is in certain cases a helpful method, though they fear the use of so strong a poison in the comparatively large doses recommended. Recent text-books all mention it and there seems no good reason to doubt that in selected cases it is the most effective treatment that there is at present.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, Held January 9, 1902.

Rowland G. Freeman, M.D., Chairman.

Hemitrophic Asymmetry.—Dr. A. Hymanson presented a patient suffering from congenital asymmetry or hemihypertrophy. The child when born weighed about twelve and one-half pounds; the labor was tedious and difficult, but forceps were not used. About six weeks after birth it was noticed that the right arm and leg were larger than the corresponding left limbs; the right thorax and abdomen were also more developed. The expression of the child was somewhat idiotic and the left face was a little more developed than the right. At the back of the head, however, there was distinct bulging of the right side of the head. The skin is soft and smooth on both sides of the body and not roughened as is often the case in hypertrophic conditions. The reflexes are normal. The infant is rather nervous and irritable during the day and is prone to be restless at night. A number of convulsions have been noticed, more noteworthy on the right than on the left. The tongue is distinctly thicker on the right side than on the left and takes part in these convulsions. There does not seem to be any hereditary element in the case. The parents are Russians and have had eleven healthy children. Twelve such cases have been reported in recent literature. As a rule all the tissues are uniformly enlarged—the skin, the muscles and the bones. Medical knowledge with regard to these cases, however, is not very definite. It is evident that theory has had more to do with the explanation of the causes of the condition than actual observation.

Rachitic Asymmetry.—Dr. Dessau said in discussing Dr. Hymanson's case that he had reported a case not long ago in which there was a decided asymmetry, though not very marked. In Dr. Dessau's case rachitis seemed to be the main etiological factor. Careful examination, however, does not seem to reveal any sign of rachitis in this patient and the case seems to be an example of essential congenital hypertrophy.

Spasmus Nutans.—Dr. Charles Hermann presented a patient suffering from the characteristic headshake of this affection. There is no heredity to be traced. The infant was breast-fed for a year and at thirteen months contracted measles, since when there has been the head-nodding. There is, as always in these cases some nystagmus; the movement of the eyes can be especially brought on by having the patient look toward the left; when the patient looks toward the right it ceases. The head-nodding is most noticeable when the nystagmus is most active.

Etiology.—Usually rickets exists as a factor in the etiology of these cases. Not infrequently the spasmus nutans begins after trauma. Sometimes it is due to the fact that the infants develop nystagmus as a result of being kept constantly in a glaring artificial light. In the present case, the method of Dr. Caillé can be employed successfully to prevent the head-nodding. His suggestion is to cover up the eyes for the time being with a bandage. When this is done or when the patient's head turns to the right and there is no nystagmus, the nodding spasm ceases. When the head is held the nystagmus can be seen more plainly. Hence it is always worse when at the breast and when the mother's attention is especially attracted to it. In the other patient a distinct rachitic condition can be found. Though the infant is seventeen and one-half months old, the fontanelles are widely open at a time when they ought to be almost completely closed. Moreover, the rachitic rosary is present on the ribs and the epiphyses of the limbs are larger than normal. Usually phosphorus is the best remedy in these cases. In one case in Dr. Hermann's experience, however, in which all the ordinary rachitic remedies failed, the patient was greatly improved by a sojourn of three weeks in the country.

Phosphorus in Rachitis.—Dr. Louis Fischer said that while it is generally conceded that phosphorus is an excellent antirachitic remedy, a decided reaction against the notion of its usefulness in rachitis is noticeable. Baginsky of Berlin says that, though he has used it to a considerable extent and watched its administration very carefully, he has not found the slightest benefit result from it. Its administration in the ordinary form of phosphorized cod-liver oil is scarcely an index of its usefulness, since the phosphorus in this preparation rapidly disappears.

Benefit of Phosphorus.—Dr. Dessau said that he has used phosphorus largely and has often obtained excellent results. He has commonly not used it alone but as the elixir of phosphorus of the United States Pharmacopœia. Since the introduction of this remedy some fifteen years ago, he has employed it in combination with cod-liver oil; he is not absolutely certain whether it is the cod-liver oil or the phosphorus that produces the good results, but certainly the patients recover more rapidly than before. He wishes it to be distinctly understood that he is a believer in the use of phosphorus for rachitis.

Trauma and Fright in Spasmus Nutans.—Dr. Stokes said that he has had the opportunity to see some six cases of spasmus nutans. In none of them were there any signs of rachitis. In a recent case the nystagmus developed suddenly as the result of an accident. The child was seated on a chair which, by the touch

of a spring, can be converted into a baby carriage; the spring was accidentally touched and the chair suddenly dropped into its lower position, the child was very much frightened, had a series of nervous symptoms and then nystagmus developed with later nodding of the head.

Effect of Heat on Cow's Milk.—Dr. S. H. Dessau read a paper on the use of heat as a modifying agent for the preparation of infant's food. Up to the present time heat has been considered useful for the preparation of baby food, mainly because it destroyed pathogenic germs. It has come to be realized, however, that certain chemical changes are induced in the milk by heat and that these may or may not be of assistance in the digestion of the milk. Fresh milk is a raw product and as such is not as digestible as cooked material. There is a marked contrast between the vomit of the cow's-milk-fed child and one fed on breast milk; the small curds, soft and soluble, of the breast-fed infant are well known. Clinical experience has shown that this is due to the difference in the digestibility of the two milks. The curd of sterile cow's milk is much more like that of breast milk; some chemical change would seem to have been induced in cow's milk that causes it to curdle in a manner more suitable for infant indigestion. Every housekeeper knows that rennet will not curdle boiled milk. It is important, however, not to raise cow's milk to too high a temperature. Sterilization at a high temperature seems to cause chemical changes in the salts of the milk that make them insoluble. As the result of the lack of these salts in the food, the infant is liable to scurvy; the antiscorbutic elements of the food are destroyed. This is true of the phosphates also and so the antirachitic elements in the milk are destroyed. The effect of heat upon food materials and their digestibility has never been sufficiently recognized. Professor Remsen of Johns Hopkins showed that the effect of heat is much more than has been thought, its principal effect being the aid to digestion if the temperature used be not too high. In Dr. Dessau's experience this use of a moderate amount of heat up to about 140° F. is much better than the attempted imitation of mother's milk. This latter is an extremely intricate problem and one that can not be solved readily under ordinary household conditions.

Anaerobic Bacteria in Milk.—Dr. J. Lumley Bell of Englewood, N. J., said that while it is well known that ordinary microbes are destroyed by sterilization, it is not known that anaerobic bacteria are destroyed by any temperature under that of the boiling-point. Very little is known of these micro-organisms, but it is beginning to be realized that they are probably pathogenically active in the intestinal tract much oftener than has been thought. While heat may destroy ordinary germs and so improve the quality of milk and may add to its digestibility by modification of the chemism of the milk, it cannot be of avail in making good baby-food out of poor milk. When microbes have continued to multiply in milk for a number of hours, certain of their soluble toxic products are dissolved in the milk and these, of course, will not be destroyed by heat. During the warm weather when microbes multiply so rapidly it is the presence of these toxins rather than the germs themselves that causes the serious effects upon the infantile digestive tract.

Coagulation by Gastric Juice.—Dr. Max Einhorn said that in his experience boiled milk coagulates as readily when mixed with gastric juice as raw milk. His experiments, of course, were conducted with the stomach-contents of adults, but he knows that the same thing would happen also if the gastric juice of infants were employed. Any dilution of cow's milk causes it to coagulate in a manner much more nearly resembling the curdling process of human milk. Dilution with barley-water suffices for this purpose.

Boiled Milk and Constipation.—Dr. Louis Fischer said that the boiling of milk for infant's food causes an extreme form of constipation. Milk that is only pasteurized has a much more constipating tendency than raw milk. During the last year Dr. Fischer has had a number of children under observation who were being fed on milk that had been sterilized according to the direction of Professor Russell of Wisconsin, the milk being raised to a temperature not above 150° F., which suffices according to Professor Russell's observations in destroying the bacteria in the milk. Even when milk is raised only to this temperature, it still proves somewhat constipating. The ideal in infant-feeding of cow's milk is a milk certainly free from bacterial contents fed at human temperature. There are several dairies in the city now that supply practically sterile milk should be subjected to this temperature for not cubic centimeter may very well be neglected. Milk from grocery-stores, however, often contains several millions of bacteria to the cubic centimeter, and this sort can not be rendered innocuous by boiling.

Heated Milk and Scurvy.—Dr. Rowland G. Freeman said that in the American Pediatric Society investigation of the cause of scurvy among children in this country, it was found that most of the patients had been fed on patent food, very few on sterile milk, so the scorbutic condition was evidently a consequence of unsuitable food rather than of any special change in the food. A certain number of cases of scurvy have been found to occur also in breast-fed children. In Dr. Freeman's experience, heating has no effect on the curdling of milk; boiled milk will coagulate in just as large curds under unfavorable conditions as will raw milk. Dr. Freeman does not think that the heating of milk to 140° F. for ten minutes is sufficient to destroy the micro-organisms in it; he thinks that a temperature of at least 160° F. should be employed and that the milk should be subjected to this temperature for not less than half an hour. This temperature is necessary especially in the case of delicate or ailing children.

Imitation of Human Milk.—Dr. Dessau said that the fad for trying to make imitations of human milk reminds him of the old-time search for the philosopher's stone; cow's milk and human milk are entirely different things. Though they contain what seem to be the same ingredients, though in different proportions, it is probable that some of the ingredients at least are of entirely different natures in the two compounds It is probable that the feeding of milk direct from the cow before it cools would be one of the most healthy ways of supplying infant food, but, unfortunately, this is not possible under ordinary circumstances, and the next best thing seems to be the proper preparation of milk food by judicious heating.

Childrens' Stomach-Contents.—Dr. Louis Fischer reported a series of observations on the chemistry of infants' stomachs, not with the idea of adding anything new to the knowledge of this subject, but in order to confirm and amplify the knowledge obtained by previous observation. He procured the stomach-contents in a certain number of children by siphoning off the material one to two hours after feeding. Most of the stomach-contents, however, were obtained from the vomit of children. In only two cases was there failure to find hydrochloric acid. One of these children was suffering from rachitis and the other was in very poor general health. It is evident that hydrochloric acid is not often absent from childrens' stomachs. The most successful treatment for the absence of hydrochloric acid in Dr. Fischer's hands is the use of external fara-

dization and the two drugs nux vomica and hydrochloric acid in drop-doses three or four times a day. After the use of these remedies for some days hydrochloric acid is found on subsequent examinations. As a rule hydrochloric acid is absent when high temperatures are present. Dr. Fischer did not find this rule, however, to be so absolute as has been claimed from the results of previous observations. In a case of measles when the temperature was 105° F., hydrochloric acid was absent, though it had been present before and was present shortly afterward. In a case of scarlet fever Dr. Fischer found traces of hydrochloric acid, though Lee says that hydrochloric acid is always absent during the active course of this fever. At the time that traces of the acid were found the child's temperature was 105° F.

Free Hydrochloric Acid in Children.—Dr. Einhorn years ago in making a series of observations on the contents of childrens' stomachs found free hydrochloric acid was present in only two cases. All of the children that he examined were perfectly normal; combined hydrochloric acid was present, but not the free acid. The gastric acidity in the child is as a whole lower than that of the adult; the albuminates of the milk, which forms the almost exclusive diet of children, combines with the hydrochloric acid, and so does not exist free in the stomach. The acidity that is noticed in the vomit of children is lactic acid and not hydrochloric acid. In febrile conditions in adults there is an inhibition of gastric secretion; this is true not only for the hydrochloric acid, but for the other elements of the gastric juice. This rule holds also for children. In typhoid fever as a general rule hydrochloric acid is very limited; in patients at the German Hospital, however, Dr. Einhorn was able to find some cases in which even free hydrochloric acid was present. It is probable that fever seldom completely inhibits the secretion of acid.

Massage in Gastro-Intestinal Conditions.—Massage is not a therapeutic measure that can be recommended on general principles for gastro-intestinal disturbances; if wrongly applied it may do harm; Dr. Einhorn has seen a case of localized peritonitis occur as the result of overzealous massage in an unsuitable case. In patients suffering from enteroptosis massage will almost surely do more harm than good. It is no uncommon experience, however, to find that patients suffering from this condition have been recommended by physicians to take massage. In children massage may much more easily do harm than in adults.

Tests for Gastric Acidity.—Dr. M. I. Knapp, when told that Congo paper was used to determine the presence of hydrochloric acid, said that this was extremely unreliable, as Congo paper reacts to acetic, succinic, oxalic, formic and in a word to all the organic acids that may be present in the stomach in small amounts; also to monophosphate of magnesium and certain other salts. Conclusions drawn from tests made with Congo paper are exceedingly unreliable. The best test for free hydrochloric acid in the stomach is made with ammonic citrate of iron according to the method recently suggested by Dr. Knapp.

Abdominal Massage.—Dr. Knapp said that abdominal massage, if not applied with great care, may easily do very serious harm. He has seen a number of bad results. Massage may be employed with benefit over the lower part of the abdomen, but not over the stomach. Massage of the epigastric region, when there is any true gastric disturbance, is almost sure to do harm, though it is often recommended.

Bilious Vomiting.—This is a symptom that, according to Dr. Knapp, is often said to occur, but without sufficient reason. True bilious material is seldom contained in the vomit. Bile should always be tested for by Pettenkofer's or some other method before the case is pronounced one of bilious vomiting. The mere greenish yellow color of the vomited material with the bitter acid taste is not sufficient to demonstrate its biliary origin, or even to prove an admixture of bile present. This greenish material will often be found to be a pure culture of mould.

Hydrochloric Acid and Prognosis.—Dr. Fischer is inclined to think that the presence of hydrochloric acid in certain infectious diseases may prove a sign of a good prognosis in cases in which ordinarily hydrochloric acid is absent. In some recent cases of septic diphtheria, in which the prognosis was very bad, Dr. Fischer found only one patient in whom free hydrochloric acid was present during the course of the disease, and this was the only patient that ultimately recovered. In septic diphtheria, the fever is usually very slight and the absence of hydrochloric acid is not due to high temperature, but to functional inhibition from general prostration.

Massage in Children.—Dr. Fischer has used massage very extensively in children, and is more gratified with the remedy the more he employs it. For atonic constipation this remedy presents the best possible method of treatment. In gastric disturbances dependent upon poor circulation, abdominal massage does excellent service. In gastric cases generally, however, the sheet anchor in treatment must be nux vomica and dilute hydrochloric acid.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Stated Meeting, Held January 2, 1902.

The President, Alexander Lambert, M.D., in the Chair.

The Personal Liberty Plea as Made Against Medical Legislation.—Dr. Floyd M. Crandall read a paper with this title. He said that he was led to write it by the fact that every attempt to advance the standard of medical practice in this country is invariably met by the complaint that the personal liberty of some of the citizens of the State is threatened. The last argument of this character was that recently made by Mark Twain while speaking in favor of the osteopathic bill before the New York Legislature. Dr. Crandall's paper is an answer to these arguments. Unlike Mark Twain, who is an educated man, there are tens of thousands of people who are unable to judge either of the character of the practitioner or of his treatment. The only protection for these unprotected thousands is the guarantee afforded by the State contained in the license to practise. Medical laws are not enacted for the benefit of the medical profession, but for the good of the people. The medical profession does not enjoy privileges which it is not willing to share with others. It asks only that it be not discriminated against by allowing those to practise who are only partially qualified. It asks only fair play and that all be treated alike. It asks that all who are granted the privilege to treat disease shall be obliged to enter at the same door—that there be no subterranean passages or short cuts. To require certain qualifications of some and to permit others to enter with less would be a blow against personal liberty and equal rights. Absolute liberty can only be found in solitude. It cannot exist in civilized society, for something must be yielded by each individual when he comes in contact with others. Restrictive laws are necessary and are designed for the protection of the many against the few. There is a vast difference between liberty and license, which the argument of Mark Twain completely ignores. He

adopts the old fallacious argument that because the State allows religious liberty, no restriction should be put upon the practice of medicine. The two questions are so dissimilar that the argument is utterly worthless. Religion is a matter of faith and belief; the practice of medicine is a matter of acts. Religion is the relation between man and his Creator; the practice of medicine is a relation between man and man. The American State does not interfere with beliefs, only with acts. The services of religion, being between man and God, come rarely, therefore, under the jurisdiction of the State. The practice of medicine, on the other hand, being a relation between man and man, must continually come under its jurisdiction. It is a fallacious argument, therefore, to hold that because one requires but few restrictions, the other also requires but few. Were it not for the fact that the arguments advanced by Mark Twain are repeatedly heard, it would seem waste of time to argue that the State in requiring certain necessary qualifications is not abridging the liberty of its citizens. It would seem almost childish to contend that the State does not use unfair discrimination in requiring the same qualifications for all, and that those who have fulfilled its qualifications are not the recipients of special favors.

In the discussion Dr. Frederick Holme Wiggin said that in talking with the members of the Legislature with regard to these matters, he had found that the great difficulty in the past had been that the Legislature and the public generally believed that whenever physicians had endeavored to improve the standard of the practice of medicine they had done so entirely from selfish motives. Probably this feeling had originated from the fact that in earlier times regular physicians had opposed the practice of irregular physicians or eclectics because they differed on matters of treatment. So long as objections were made to a class of individuals because of differences of opinion of this nature failure would result. On the other hand, if efforts were directed to securing the licensing only of those having the proper qualifications, a good deal should probably be accomplished. This was like requiring an engineer to have a proper knowledge of the steam engine before being allowed to run one. In time there might be one general examining board. So long as there are various examining boards for so-called different schools of medicine, this strife would probably go on.

Dr. Parker Syms said he thought the weakness of the efforts in the past had apparently arisen from insisting too much upon mere methods of treatment. It was certainly this in the past which had given strength to the homeopaths. It was now well known that the vast majority of diseases could be successfully treated without drugs, and yet they were almost invariably treated by means of drugs. For this reason almost any kind of a healer must succeed in a large proportion of cases. Efforts should be directed to improving the standard of education for regular practitioners, leaving others out of consideration. The reader of the paper had very properly suggested that the standard of education should be raised, not in the schools, but by means of systematic post-graduate education. This could best be brought about by working together, all the specialists contributing to the general fund of knowledge.

Some Clinical Aspects of Chronic Non-Alcoholic Gastritis.—Dr. George R. Lockwood was the author of this paper. He said that an analysis of symptoms presented in a large series of cases showed great variation from the traditional course of the disease. The cases were divided into those with high acidity, normal acidity, and low acidity. Those with high acidity complained either of hyperacidity, "biliousness," or of diarrhea without lesion in the colon. Those with normal acidity were anemic and constipated. Those with low acidity were neurasthenic, poorly nourished, complained of "biliousness" or of diarrhea; nausea did not occur, nor did any patient vomit. The appetite was uniformly good. Gas occurred only when there was atony. Tests showed in the gastric contents of these cases no fermentation whatever, even when the gastric contents were kept at blood temperature for days.

Dr. Alexander Lambert in discussion asked the author whether he had found that oxaluria was a feature in these cases. He did this because he had found a number of patients presenting the digestive symptoms described in the paper and associated with oxaluria.

Dr. F. W. Jackson said that he was supposed to open the discussion, but he did not see how this could be done. All present must feel like thanking Dr. Lockwood, and congratulating him on his very instructive paper. If the position taken in the paper were to be accepted it was evident that there must be great difficulty in making the diagnosis. He wished Dr. Lockwood, in closing the discussion, to give some points in the diagnosis of gastritis which might be of service to those who were not experts in making gastric analyses. Physicians frequently met with secondary anemias without focal symptoms, and if the anemia were due to gastritis the physician should be able to ascertain this.

Dr. H. S. Stokes said that he had found a good deal of difficulty in general practice in securing the consent of the patient to washing out of the stomach, though many would consent if it were insisted upon by a specialist.

Dr. Lockwood replied that he had had only two persons refuse to submit to the treatment.

Dr. H. H. Seabrook asked how the atonic cases were distinguished from the others.

Dr. Lockwood said that this was one of the most difficult problems in gastric work. If, when in the fasting condition, six ounces of water when put into the stomach produced a splashing, such a stomach was atonic. When atonic, food would be retained longer than proper. There were, of course, conditions of temporary atony connected with a cold or perhaps with an attack of grip, but this would soon pass off. In the hyperacid cases there was some retention. He had made experimental lavage an important differential point, in cases of prolonged food retention, between atony and prolonged food retention with contracted pylorus. In cases of contracted pylorus, all of the water was returned; in cases of atony there was a large quantity of residual fluid. As the cases under intragastric faradization improved the stomach would be found able to expel the water introduced. Replying to the question as to the relation between oxaluria and gastritis, Dr. Lockwood said that oxaluria was probably dependent upon functional disturbance of the liver arising from the presence of abnormal products in the blood, these abnormal products being the result of perverted function of the stomach. Oxaluria, however, bore no relation to acidity or hyperacidity. In answer to Dr. Jackson, he would say that one should suspect gastritis (1) in any long continued gastric neurosis; (2) in all cases of biliousness and functional disturbance of the liver; (3) in all cases of persistent diarrhea; (4) in all cases of anemia and constipation not readily controlled by treatment and without apparent cause, and (5) in all melancholias or cases of depression, and in cases of causeless neurasthenia.

EASTERN MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held January 10, 1902

The President, R. Abrahams, M.D., in the Chair.

A case of "Amaurotic Family Idiocy" was presented by Dr. A. Hymanson. Dr. Schapringer demonstrated the eye lesions of the same case. A case of "Bullous Eruptions in a Child" was presented by Dr. Willian. S. Gottheil. A case of "Ulcer of the Esophagus" was reported by Dr. M. I. Knapp.

Otitis Purulenta in Infants.—This was the title of a paper read by Dr. Max Toeplitz. After a brief description of the anatomy of the ear in the newborn and infant, with especial reference to the difference from that of the adult, Toeplitz emphasizes the position of the mucous cushion of the tympanitic cavity at birth, for the question of existence and future development of the so-called otitis media neonatorum. This is not acknowledged as an independent disease, as proven by the numerous autopsies on children whose middle ears were found to be filled with pus, in, or without, connection with other diseases. He then describes the two forms of otitis purulenta, their symptomatology, course, duration and complications, particularly in acute infectious diseases. The causes of otitis purulenta are then exhaustively treated as well as its bacteriology and frequency of occurrence. In conclusion, the treatment is briefly sketched and the indications for operations (paracentesis, mastoidotomy) are well defined.

Dr. Edward Fridenberg, in opening the discussion, called attention to the difficulty in diagnosing otitis in infants; in these young patients it may be mistaken for typhoid fever, meningitis, etc., until the spontaneous rupture of the drum membrane, when the symptoms suddenly abate. He emphasized the importance of routine examination of the ear by the general practitioner. Dr. Fridenberg stated that 90 per cent. of all chronic otorrheas in children are due to extension of an inflammation from the nose and throat to the ear, particularly in cases of tonsillitis, measles, scarlet fever, etc.

The Indications for the Surgical Treatment of Cholelithiasis.—Dr. A. A. Berg said he considered that those cases of cholelithiasis that manifest themselves by cholecystitic pain and attacks of biliary colic uncomplicated by cholecystitis were benefited by medical treatment. Great severity or constancy of these symptoms in spite of medical treatment called for surgical intervention. The first attack of acute cholecystitis accompanying calculous disease of the gall-bladder formed a strong indication for the abandonment of the medical and a resort to surgical treatment. For even though the acute attack subsided the secondary infection of the gall-bladder and ducts by the bacteria which gave rise to the acute cholecystitis, did not pass away. These bacteria remained residents of the gall-bladder and ducts, exciting from time to time fresh attacks of cholecystitis. In the apparently quiescent periods between these acute attacks, they are giving rise to local lesions, and by their life and development to a chronic general intoxication, the latter manifesting itself by fatty and waxy degeneration of internal organs. The toxemia is especially important, and to it is ascribed the debilitated and emaciated condition of the patients who have suffered for a long time with attacks of acute cholecystitis. Dr. Berg considers that early operation after the first attack of cholecystitis will avoid these serious local and toxic complications. As a rule operation is not imperative during the first acute attack of cholecystitis. This is because the great elasticity of the gall-bladder enables it to accommodate even considerable quantities of inflammatory products without these latter becoming under much tension. This attribute of distensibility also explains the infrequency of perforations of the gall-bladder, as compared with the appendix. Operations during the acute attack are indicated by a marked intensity of the local and general manifestations, otherwise the operation can be postponed until the quiescent period after the attack. To delay and procrastinate until an empyema or gangrene of the gall-bladder has taken place, or until cholemia, infective cholangitis, obstructive jaundice or perforation has occurred, is unjustifiable and unwarranted. The mortality after early operations is 2 to 3 per cent., whereas the death-rate in the later complicated stages of the disease rises over 50 per cent., even in the most expert hands.

Dr. Berg's conclusions may be stated as follows. (I.) Indications for medical treatment; cholecystitic pain or attacks of biliary colic, in either case unattended with fever. II. Indications for medical treatment; (1) operations of choice, undertaken in the quiescent period, with the object of avoiding serious complications; a simple procedure and followed by 2 to 3 per cent. mortality. (*a*) Severe cholecystitic pain or oft-repeated biliary colic, persisting in spite of medical treatment, in virtue of which symptoms the patient becomes an invalid and incapacitated for work. (*b*) After the first attack of acute cholecystitis, associated with fever. (2) Compulsory operations; undertaken at any time of day or night, often amidst unfavorable surroundings and in patients who are skeptic, emaciated and of low vitality. Difficult and laborious procedures and attended with high mortality—50 per cent. (*a*) Intensely acute attacks of cholecystitis. (These may be the first indication of calculous disease, but usually follows previous milder attacks.) (*b*) Hydrops, empyema, gangrene or perforation of the gall-bladder, cholemia, abscess of the liver, and diffuse peritonitis.

Dr. A. G. Gerster opened the discussion and stated that he wished to insist that the most important point in the treatment of cholelithiasis is first to make a diagnosis. This is not always easy. Some cases are diagnosed by the patient himself, but others are very difficult of diagnosis and tax the skill of the most experienced. This is particularly the case with some women whose liver and gall-bladder are situated high up in the abdominal cavity and covered by the lower part of the right thoracic wall. Dr. Gerster considers that a well and carefully established anamnesis, particularly as to paroxysmal pains in the abdomen, the most important aid in diagnosis. After eliciting a history pointing to gall-stones, careful palpation may reveal a pear-shaped tumor which ascends and descends with the movements of respiration. He then emphasized the importance of abdominal palpation in cholelithiasis. As to treatment, Dr. Gerster is of the opinion that medical treatment is to no avail, excepting for immediate relief. Surgical treatment is the only means of permanently curing these sufferers.

Dr. A. E. Isaacs took exception to the statement that biliary colic without suppuration in the gall-bladder is not attended by elevation of temperature. He has frequently observed cases of acute cholelithiasis in which the thermometer registered from 102° to 105° F. While Dr. Isaacs does not exclude the possibility that the pus in the gall-bladder might in these cases have followed the exit of the stone, still the fact remains that elevation of temperature during an attack of biliary colic is no proof of dangerous suppuration in the gall-bladder. Dr. Isaacs does not think that operation is indicated in all cases of cholelithiasis. Many people have several attacks of biliary colic and then remain free from it for the rest of their lives.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Annual Meeting, Held January 13, 1902.

The Vice-President, William McCollum, M.D., in the Chair.

Election of Officers.—The following officers were elected: President, Dr. Andrew H. Smith; Chairman for the Borough of The Bronx, Dr. S. Carrington Minor; Member of the Executive Council, Dr. Reynold W. Wilcox.

Treatment of Urethral Strictures.—A discussion on the treatment of urethral strictures was opened by Dr. Ramon Guiteras. Strictures were classified, he said, as anterior and deep, the former being situated between the meatus and a point within an inch of the cut-off muscle and the latter between this point and the posterior urethra—thus including the membranous urethra and the inch in front of it. He reviewed the causes, symptoms and diagnosis of stricture, stating that the most dangerous symptom, or rather complication, was an acute attack of retention. It usually occurs in strictures of small size, deeply seated, when, owing to some exposure, dissipation or reinfection, there has been sufficient congestion about the stricture to render it impassable, or nearly so. Usually strictures of small size, that is those below No. 15 French, are the ones that give rise to serious urinary symptoms. In general terms it may be said that all strictures, whether large or small, anterior or deep, that can be dilated, should be treated in this manner. All others should be operated upon if they give rise to symptoms warranting such a measure. In order that the urethra may be intelligently examined, a small meatus, due to congenital narrowing or linear stricture just behind the meatus, should be cut to No. 32 or No. 34 French, if, as is usually the case, it cannot be dilated.

Dilatation.—The three methods of dilatation are the continuous, the gradual, and the rapid. The first is usually employed in strictures of small caliber which admit only a filiform or a very small olivary woven catheter. After one of these instruments has been introduced it should be allowed to remain in position for twenty-four hours, the patient passing his urine along its side. A larger one is then introduced, and allowed to remain for the same time; and so on, until the dilator or sound can be introduced and the narrowing can be gradually dilated. Gradual dilatation consists in passing dilators or sounds every few days until the urethra has been stretched to the normal size, or as near the latter as possible. In rapid dilatation the size of the urethra is increased in one or two sittings, and it is particularly applicable to such patients as feel that they cannot submit to operation and have not the time for gradual dilatation. Personally, Dr. Guiteras said, he did not favor this method, although he had seen the most admirable results accomplished by the Newell dilator. Most dilators are of large size (over No. 15 French) but the Newell instrument is No. 8 French, and is passed connected with a filiform guide. Dilators are especially efficient in the treatment of strictures of medium caliber, *i.e.*, from No. 18 to No. 20 French, and the best instruments are those of Oberlaender and Kollman. Dilators should never be introduced unless enclosed in a rubber cover, well lubricated with sterilized lubrichondrin; and in office work it is well to boil the instrument, with the cover on, before introducing it. Sounds, of course, are and always will be useful, their employment constituting the most general means of dilatation; and the heavier the sound, the better. In dilating either with sounds or with dilators the stricture should not be increased more than one or two millimeters at each dilatation, and afterward the canal should be washed out with a nitrate of silver solution of a strength varying from 1-600 to 1-4,000.

Operative Treatment.—All strictures that cannot be dilated should be cut. All narrowing of the navicular fossa should be cut on the floor of the urethra with a blunt-pointed bistoury, with the exception of cases of balanic hypospadias, in which the incision should be directed upward to the roof. Anterior strictures of large size (over No. 15 French) that will admit an Otis urethrotome should be operated upon with this instrument, the incision being made in the median line of the dorsum of the canal. Those of small size should be cut with the Maisonneuve urethrotome in the roof of the canal. Strictures of sufficiently small size to give rise to annoying symptoms should be cut externally through the peritoneal urethra on a grooved guide, tunneled sound, or catheter that has been passed through the urethra beyond this point. When anterior and deep strictures are both present the method adopted should vary according to the circumstances of the case.

Having described the method of operating in impermeable strictures, Dr. Guiteras expressed the opinion that the actual number of such strictures was very small, and said that in the last five years he had encountered but one case in which he was not able to pass an instrument. With filiform bougies and a good lubricant he thought that almost any stricture could be passed, especially if the patient be put to bed and treated with diluents, hot sitzbaths, hot applications, and antispasmodics for a few days. He said he spoke strongly on this subject of passing guides through a stricture before operating, because he felt convinced that the patient stands a much better chance of recovery when the surgeon can make a straight clean cut through a stricture on a guide than when he flounders about in the dark in a bleeding perineum, stabbing at the neck of the bladder in the hope of opening it behind the stricture. He aways tries to pass a filiform or flexible guide before operating; if not successful and if the case is not an urgent one, he postpones the operation and makes further attempts on other occasions, until he succeeds in passing it. After it is once passed it is tied in until the day and hour of operation, and sometimes a patient remains in bed for three days before he is operated on, passing his urine by the side of the instrument thus retained.

Treatment Before and After Operation.—The treatment of a patient before operation consists in promoting free diuresis with large quantities of water, the administration of urotropin (15 grains three times a day), and the washing out of the bladder twice a day, provided the stricture is of sufficiently large caliber to permit the passage of a catheter. After operation the free diuresis and use of urinary antiseptics should be continued. After internal urethrotomy sounds should be passed at the end of forty-eight hours, and then every two days while the patient is confined to the house or hospital. After external urethrotomy the whole urethra is flushed out with hydrogen peroxide, and then with boric acid solution. A large thick-walled catheter, No. 40 French, is inserted through the perineal opening, pinned to the side of the incision and packed about with gauze. While the urethra and bladder are washed out twice a day with boric acid solution, the dressing need not be changed for forty-eight hours, when the tubes are taken out and sounds passed. The sounds should be passed every two days, the tubes (which should be employed for from four to six days) always being withdrawn before their passage. For a considerable time the

patient's bladder should be washed out through a catheter with a weak solution of nitrate of silver.

Pathology of Stricture.—Dr. Robert H. Greene said he believed that all pathologists were agreed that stricture follows a granuloma or ulceration which in the great majority of cases is preceded by a urethritis. This process may make a soft band in the urethra which has often been operated upon for stricture. It is in reality not a stricture at all. These facts are generally acknowledged; but there are two questions which have not been definitely settled, viz.: (1) How long does it take this cicatricial tissue to develop in a urethra which has not been wounded with instruments? (2) Does this process of cicatrization ever go on in a urethra not wounded to such an extent as to necessitate a cutting operation? Operations upon strictures of large caliber had apparently been done away with in the last few years, and he thought that surgeons were deserving of much credit on this account. It seemed to him that at the present time the majority of authorities consider stricture, following urethritis, of such severity as to require operation quite rare in those under forty. In men older than that the cicatricial tissue forms faster. The second question, Dr. Greene said, was very difficult to answer because almost all the strictures which are cut give a history either of previous operation or of the careless use of instruments. Personally he believed that a man who has never had his urethra wounded, thereby facilitating the formation of cicatricial tissue, will never have a stricture so severe as to require cutting, although such stricture may require dilatation. In one of the hospitals with which he was connected he saw a number of cases in which there was such a mass of connective tissue in the bulbomembranous urethra that an operation was required. He generally did a perineal section and also an internal urethrotomy, if required, using either an Otis or a White urethrotome. As to external urethrotomy, he thought the incision should be as limited as possible. Whether there were any hemorrhage at the time or not, the parts should be well packed during the operation, as he had seen severe secondary hemorrhage in cases in which this was neglected. In conclusion he exhibited a new filiform bougie manufactured by Tiemann, which was constructed of catgut and which could sometimes be made to pass when the ordinary filiform bougie failed. It was superior, he thought, to the Banks bougie, which was made of whalebone.

Characteristics of True Stricture.—Dr. Wm. K. Otis said that the formation of stricture was practically the formation of scar tissue which entirely surrounds the urethra. Unless the scar tissue does entirely surround the canal stricture does not exist. Plaques on one side do occur and are composed of cicatricial tissue, but they cannot be detected by means of bulbous bougies, etc. When, however, such tissue surrounds the urethra it goes on steadily contracting, and so gradually narrows the caliber of the canal at one point until it becomes an annoyance to the patient. After dilatation the trouble will return, and it will do so indefinitely whenever the dilatation is discontinued. When a stricture had become thoroughly organized he did not believe it could be cured by dilatation. As soon as it has been divided by a clean cut the stricture ceases. The ends spring apart. The cicatricial tissue may go on contracting, but after it has been severed with the knife it no longer diminishes the lumen of the canal. He could not agree with Dr. Greene, and said that he had known of many instances in which instruments had never been used on the urethra in which strictures had gone on to retention of urine and in which the smallest filiform bougie could not be passed.

Narrow Strictures Must be Cut.—Dr. Otis said that when it was necessary to operate on a patient he did not take as much time as formerly in trying to pass filiform bougies. When filiform bougies can be passed only with difficulty, or when it is necessary to employ special forms of such bougies, the case is one that requires operation. The stricture can no doubt be dilated, but the patient's life is in danger the moment he gets beyond the reach of a competent surgeon.

Patience and Perseverance Generally Successful.—Dr. James Pedersen said there were undoubtedly many cases which could be better treated by dilatation than by cutting. He had seen strictures so small that a filiform bougie could scarcely be made to pass, yet in which careful manipulation proved very satisfactory. It was true that the stricture was not really cured, but the patient had been placed in a condition which made him quite independent of the surgeon. In illustration he narrated a remarkable case of Dr. Bangs' in which patience and perseverance had been entirely successful in the end, while the patient had not been at all debarred from his usual business and pleasures.

Dr. Robert W. Taylor said he had no faith in what are called large strictures. When preparing his book he made a great effort, through efficient and painstaking assistants, to find out what these cases were, and he had been able to secure only one instance. In this case there was a small band, about half an inch in length, which ended to the right of the median line. Only twice in the last two years had he seen a true stricture in men under twenty-five, and in one of the cases the patient had become infected when only twelve years old. Under the age of thirty-five men have what is known as soft stricture, consisting of granulation hyperplasia.

Divulsion Condemned.—Dr. Taylor condemned in the strongest terms the dilators devised by various surgeons. He designated Holt's as "an instrument of death," and said he hoped that Oberlaender's and Kollman's would never come into vogue in this country. In the abandonment of such ruthlessly dangerous instruments he thought there had been a great advance in the last few years. It was the mild force that accomplished the desired purpose. Gradual dilatation with straight sounds or olivary bougies should be practised. Plenty of time should be taken with stricture cases, and the sounds should not be passed too often. Above all, careful and systematic treatment of the urethra with nitrate of silver solutions is essential. By these means the great majority of cases can be cured without cutting. When the latter is necessary the Otis urethrotome is the most satisfactory instrument for the purpose. In cases in which after a persevering trial of dilatation a sound larger than No. 15 cannot be passed without causing great irritation, it is advisable to practise external urethrotomy first and afterwards internal urethrotomy.

JOINT MEETING OF THE CHICAGO MEDICAL SOCIETY WITH THE CHICAGO SOCIETY OF INTERNAL MEDICINE.

Held January 29, 1902.

Symposium on Cirrhosis of the Liver.

The first paper was read by Dr. Arthur R. Edwards, who said that Rosenstein suggested three classes of cirrhosis, namely, (1) the genuine contracted liver, the cirrhosis of Laennec, an analogue of the genuine contracted kidney; (2) the hypertrophic icteric cirrhosis, an analogue of the parenchymatous nephritis; (3) the

hypertrophic mixed form, in which hypertrophy and atrophy combine, an analogue of the secondarily contracted kidney.

Gilbert and Surmont made the following classification: (1) Biliary cirrhosis. (*a*) Hanot's biliary hypertrophic cirrhosis; (*b*) biliary cirrhosis due to obstruction of the bile vessels, with infection; (*c*) experimental biliary cirrhosis due to ligature of the bile vessels and infection of the same; (*d*) biliary cirrhosis in the lower animals due to distomata, eggs of the nematodes, coccidium, etc. (2) Vascular cirrhosis. (*a*) From exogenous poisons, *e.g.*, alcohol, lead, phosphorus, etc.; (*b*) from autogenous intoxications, *e.g.*, dyspepsia, gout, diabetes; (*c*) infections or toxemias, tuberculosis, syphilis, malaria, exanthemata, etc.; (*d*) arteriosclerotic; passive congestion. (3) Lymphatic cirrhoses. Capsular cirrhosis; perihepatitis.

The classification he had suggested was attempted rather with a view of including the principal conflicting clinical and pathological divisions than of offering an infallible or as strictly scientific arrangement of the varieties of cirrhosis of the liver as Chauffard's. (1) Capsular cirrhosis. Also known as glissonian or lymphatic cirrhosis. (*a*) Chronic perihepatitis, isolated or part of a chronic peritonitis. (*b*) Portal vein syphilis, also vascular in origin. (2) Vascular cirrhosis. (*a*) Hepatic vein. (*b*) Stasis cirrhosis (cyanotic induration). (*c*) Laennec's cirrhosis; also that of Brieger and Sabourin, known as bivenous cirrhosis. (3) Portal vein. (*a*) Laennec's cirrhosis or atrophic. First stage, pseudohypertrophy; second stage, atrophy. (*b*) Hypertrophic alcoholic cirrhosis, like Laennec's, only remaining large; fatty cirrhosis. (*c*) Cirrhosis from portal vein, syphilis, and from pyelothrombosis. (*d*) Arteriosclerotic cirrhosis. (4) Biliary cirrhosis. (*a*) Obstruction, retentions, icterus and cirrhosis. (*b*) Biliary or hypertrophic, in French sense (Hanot's cirrhosis), with icterus or without icterus. (5) Mixed cirrhosis. Vascular and biliary varieties combined in varying proportions.

Cirrhosis in Childhood.—Dr. Frank X. Wales read a paper on this subject. Cirrhosis of the liver was one of the most uncommon diseases that occurred during infancy or childhood. The cirrhoses belonged to the decadent period of life, and it was only under the most unusual conditions that they were encountered during its ascendancy. Though similar morbid factors be evolved within the economy of the child that in the adult led to a gradual parenchymatous decay and interstitial overgrowth, still in the child the nutritive and reparative powers of the individual were sufficient to sustain and restore the hepatic parenchyma, even though seriously damaged. In children, who die as a result of some overwhelming sequel of the acute infectious diseases, the liver frequently was found to be the seat of an extensive cellular infiltration of the connective tissue, with a granular, fatty, or even necrotic degeneration of the epithelium, and so often was this seen that one might believe there was always more or less hepatic inflammation in the severer cases of infection. Klein examined the liver in eight consecutive autopsies on scarlet-fever patients and discovered acute hepatitis in all. Moreover, sufficient corroborative evidence was found clinically in the enlarged livers and subjaundiced skins that were present in the many severe infections that ultimately recovered to assume that the acute hepatitis was not confined to the lethal cases. Despite the frequency of this acute hepatitis, it was most unusual to meet with a case in which there was the slow productive overgrowth of subsidiary tissue at the expense of the granular elements which constituted the morbid picture of cirrhosis. Cirrhosis was an advanced lesion, slow and tardy in its evolution, and demanded time for its development. It was so rare a disease in the young that those who had had the largest clinical experience could count their cases in the units. Though the recent literature had greatly multiplied the number of recorded cases and some had advanced the statement that the disease was not uncommon in the child, yet the infrequency of the disease could be sufficiently substantiated by quoting the statements of a few of the greatest clinicians. Baginsky had seen four cases. Henoch had never seen the disease fully developed in children. Charles West, among 70,000 sick children, saw cirrhosis but four times. Frerich saw but one.

Male children were afflicted more often than female in the proportion of five to one. In Palmer's group, the ages varied from one month to eighteen years, and fifty per cent. of these occurred between the ninth and fifteenth years. An alcoholic history had been obtained in less than twenty per cent. of the recorded cases. In a few of these the amount of alcohol taken daily for a considerable period of time had exceeded a pint of brandy, but in most of them only a small quantity of spirits had been drunk. While the influence of alcohol in the production of cirrhosis in children was decisive, it was not so consequential as in the adult. Syphilis was mentioned as an etiological factor in about ten per cent. of the cases. Tuberculosis was a relatively frequent causal factor. The acute infectious diseases had been considered as potent causative exciters, but in no case had the evolution of the cirrhosis been unequivocally connected with the acute infections, nor had the infections occurred with greater frequency than might be considered accidental, and perhaps not oftener than in the average run of children. Chronic sepsis, particularly where there had been a chronic peritonitis, had been an occasional factor. Cirrhosis of the liver, secondary to the nutmeg liver of heart disease, had occurred only a few times. Thompson had collected a number of instances of obliteration of the bile-ducts in the new-born which was followed by cirrhosis.

Dr. Wall then discussed at length the symptomatology, the diagnosis, prognosis and treatment of cirrhosis of the liver in childhood. Of treatment of cirrhosis of the liver in children he said that therapy up to now had been fruitless. Could the disease be anticipated before the advent of the cirrhosis, one might hope for much by withdrawing those factors which might have any baneful influence upon the child, and by giving careful attention to the hygiene and diet. Much had been claimed, particularly by the French school, for an exclusive milk diet, even if the cirrhosis be established. The use of the so-called resorbent waters, such as Carlsbad, the inunctions of gray salve, and the rational fulfilment of the symptomatic indications grasped the present possibility.

Pericarditic Pseudocirrhosis of the Liver.—Dr. James B. Herrick read a paper with this title. In 1896 Pick described three cases to the symptom-complex of which he gave the name pericarditic pseudocirrhosis of the liver. Clinically, they presented relatively slight edema of the lower extremities, enlarged liver, and rather obscure cardiac findings. These cases showed postmortem adhesive obliterating pericarditis; adhesive pleuritis, and changes in the liver described as nutmeg liver, cirrhosis of the liver, coarsely granular liver. From his studies of these cases and other similar ones reported by other observers, he concluded that this symptom-complex resembling true cirrhosis was caused by a late pericarditis that induced circulatory disturbances in the liver, leading to an increase of connective tissue, in this way producing portal stasis and ascites.

Dr. Herrick referred to the importance, from a diagnostic standpoint, of inquiring into the past history for

symptoms suggestive of preceding pleurisy for pericarditis, and said that the physical signs of active or healed pleurisy should be sought for as well as those of perihepatitis. The coarser signs of pericardio-mediastinitis, such as the systolic retraction interspaces, the diastolic rebound, the paradoxical pulse, the fulness of the veins in the neck, and the feeble apex impulse, should also be sought for.

Dr. Herrick referred to three cases of this disease that had occurred in his own practice, in one of which an autopsy had been secured at which an adhesive pericarditis with calcification had been found, with extensive hyperplastic pleuritis and cirrhosis of the liver, all being due to tuberculosis. The clinical features of this case had corresponded very closely to those of the third case described by Pick. The other two patients were still living, but showed enlargement of the liver, pronounced ascites, evidence of fluid in the pleura, or of adhesive pleurisy, with symptoms and physical findings suggestive of pericardial adhesions.

He agreed with Strümpell that the cases were not all of one pattern and, though there was some justice in the criticism that had been offered to Pick's explanation of the occurrence of ascites and that one could absolutely not rule out the influence of local peritonitis, he thought further that there was a possibility that the trouble while originating in the pericardium might start from this point as a center and involve the contiguous pleura and peritoneum; in other words, that passive congestion of the liver was not an ample explanation for all the phenomena of the disease. While Pick's observations had been preceded by somewhat similar observations of others, and while one might criticize somewhat his line of reasoning, full credit must be given to Pick for having most accurately described the symptom-complex and for calling the attention of the profession to this peculiar condition.

Medical Treatment of Cirrhosis of the Liver—In a paper with this title Dr. John A. Robison stated that cirrhosis of the liver was incurable if the fibroid stage had supervened. Prior to this stage there was a small chance for recovery, especially in the syphilitic cases. The medical treatment should be considered, therefore, under three headings: Prophylaxis, the first stage of treatment, and the palliative treatment. There was no doubt that there was an hereditary predisposition to the disease in certain families, especially in those having a gouty diathesis. He believed a long line of tipsy ancestors, who had died of cirrhosis of the liver, might engraft on their progeny a susceptibility to the disease. The knowledge of such a tendency should be of great value to the patient in conducting his habits of life in a channel in which toxic products would not produce the cirrhosis.

The prevention of the disease would be easy in a large number of cases if physicians could prevent the toxic influence of ingested and autochthonous poisons. But unfortunately for the cirrhotic victims, their medical adviser's advice was seldom asked and less often followed until active signs of the disease were present. By this time the process had been aroused by poisons, infections, or arteriosclerotic changes. The problem, then, was how to arrest the disease, or if this be impossible, how to alleviate it. If the use of alcoholics be the cause of the disease, it should be stopped If malaria, the proper curative measures should be adopted; if the disease was of syphilitic origin, active antisyphilitic treatment should be established. If the cirrhosis was manifestly the result of disease of other organs, treatment should be specifically directed toward them. No matter what the etiological factor, the general management of the patient, the supervision of his daily habits, exercise, diet, and the treatment of the various symptoms must receive constant attention. The diet should be plain and simple, free from alcoholics, strong condiments, or spices, relishes, sauces, fried food, pastry, and sweets. Vegetables and fruits might be allowed, and milk should be a main staple. So far as possible, the patient should receive plenty of rest and fresh air. An outdoor life is beneficial and a sojourn in mild climates, especially at mineral spring resorts, was often beneficial. In the early stage the administration of calomel was recommended by many, on the theory that mercurials had the power of causing the absorption of fibrinous exudations. But there was no evidence to prove that mercurials had such power in the case of proliferation of connective tissue; hence the good results obtained in cases in which mercurials had been given must have been due to their action on the intestinal tract. Vomiting should be allayed by bismuth and alkalies, with the addition of thymol, resorcin, creosote, etc., if fermentative dyspepsia is present. The routine treatment of ascites in the past had been to give hydragogue cathartics and diuretics, but it was like trying to empty a vessel by pumping out as much or less water than flowed in. The drug treatment was unsatisfactory, and paracentesis should be resorted to early. The union of the liver to the abdominal wall with omentopexy would relieve the portal circulation before the ascites was established. Paracentesis should be performed early, and often, if the fluid rapidly accumulated, as the pressure embarrassed respiration and the heart's action. Opium, absolute rest, and the withholding of food from the stomach, were essential in the treatment of hematemesis. In case the diarrhea was intractable, large doses of the bismuth compounds were the safest remedies. In many cases it could not be checked, and it would be necessary to support the patient by administering the concentrated foods and alcoholics. Exhaustion should be combated by the use of tonics and restorative remedies.

BOOK REVIEWS.

Memoirs and Letters of Sir James Paget. Edited by Stephen Paget, One of His Sons. Longmans, Green and Co., New York.

There is nothing that appeals to the thinking man as the biography of another who has worked and achieved along his own lines; and there is, perhaps, nothing that so comforts the one who is striving as the knowledge that he who has won fame, has done so through no trick of fortune or accident of birth, but through the hardest work, in spite of the worst luck, and in the face of every discouragement.

The name of Sir James Paget shines before medical men with a brilliancy that dazzles them into the belief that he was born to the friendship of the great, and predestined to have kings and queens among his patients. As a famous surgeon, as an orator, an author and a scientist he is known to every one; but who knows of his frugal hard-working youth, as a surgeon's apprentice in a country town, where he taught himself French by translating Bichat's *Anatomie Générale* and took his recreation in making botanical and zoological collections?

This volume, containing his modest autobiography and many letters, is made doubly interesting by parallel commentaries written by his son, supplying information about the hospital in which he was a pupil, the hospital museum of which he was the curator at £100 per year, and, finally, St. Bartholomew's Hospital where he was for many years the warden and for many more the most popular lecturer.

No physician who is trying to keep abreast of scientific thought while earning his living can read this book without marveling at the man's energy by which he was able to fill an onerous position at a great hospital, lecture to crowded classes, support a family of six children, shoulder his family's debts, and, at the same time, be the exponent in England of the vast new scientific movement that was being born in Germany, in the laboratories of Muller and Virchow. And how many who have striven will take comfort from the frank confession, "During the first seven years after obtaining my diploma my largest income from practice was £23. 13s.; and until I had been a surgeon for sixteen years it had never exceeded £100."

After following the crowded details of his busy life, and the unnumbered hours of work in which he acquired his skill, and having passed with him through the anxiety of the risk in taking a house and launching out into surgical work, it gives one a positive thrill to read that his income steadily increased until it exceeded £10,000. Of this time he writes, "In looking back on this success I feel quite unable and unfit to judge how far it was due to my fitness for practice. I was not disqualified by any of the gravest hindrances to success, as by being habitually idle, time-wasting, unbusiness-like, unpunctual, uncivil, unable to work with others—faults which I have seen singly or together spoiling the careers of men whose knowledge might have brought them great success. Neither, on the other hand, could I assign any part of my income to self-advertisement, or sheer impudence, extortion, unfairness, or mere greediness. I think it was all so far fairly earned that I might be regarded as an example of the rule which I have often tried to impress on pupils: That any one with a safe knowledge of his profession, and free from such faults as I have enumerated, may be as certain of success in the practice of medicine or surgery, or both, as in any other business in life."

With the honors of his later life, his friendship with the great men of the century, the royal patients, his title, and his fame, all physicians are familiar, but it is a delight to read of the gradual attainments of the rewards for his incessant indefatigable work and patience, for one cannot help but feel, after this intimate revelation of his daily life, that he was as lovable as he was clever, and that he was as great as he was famous.

A Practical Guide to the Administration of Anesthetics. By R. J. Probyn-Williams, M.D., Senior Anesthetist and Instructor in Anesthetics at the London Hospital; Lecturer on Anesthetics at the London Hospital Medical College; Assistant Anesthetist at the Dental Hospital of London. Longmans, Green & Co., London, New York and Bombay.

To furnish a book on anesthesia which is more brief and accessible than the larger works of Hewitt or Buxton is the design of the author. The opening chapters all too briefly consider the effects of normal anesthesia, the various stages of general anesthesia, and the difficulties and dangers attending it. Nitrous oxide, ether, chloroform, and their various mixtures are given long and important chapters. The author considers ether safest in abdominal surgery, but finds that in some operations the deeper respiration caused by ether is troublesome to the surgeon, or a long operation may be accompanied by such excretion of mucus and saliva as to increase the danger of bronchitis or pneumonia. Then, too, ether stimulates so much that when its effect is worn off a grave condition of collapse may supervene. He recommends beginning with gas and ether and changing, after half an hour, to the A. C. E. mixture, or even to chloroform. The use of anesthetics in midwifery is dismissed in two paragraphs. The author gives the anesthetic which he prefers at different ages, and closes with a very brief chapter on local anesthesia. Undoubtedly this book is a good one for the student to have, and experienced men may glean from it valuable suggestions.

Transactions of the American Otological Society. Thirty-fourth Annual Meeting, July 16, 1901. Vol. VII. Published by The Society. Mercury Publishing Company, Printers, New Bedford, Mass. 1901.

This number of the Society's Transactions contains the portrait of the lately-deceased Dr. Henry D. Noyes, a life-long member and one of the founders of the Society, whose memorial, written by Dr. Gruening, accompanies it.

The ten papers presented were not of that absorbing interest which one would naturally expect in papers read before the representative national society. The herpes cases associated with mastoid disease and ending in death from meningitis make valuable records, though no attempt is made to explain them. Knapp's cases of sinus thrombosus are in the full tide of advanced work in aural surgery and they elicited full discussion.

The usual Index of Otological Bibliography is really the most valuable feature of the volume.

Manual of Bacteriology. By Herbert W. Williams, M.D., Professor of Pathology and Bacteriology, Medical Department of the University of Buffalo. Second Edition, Revised and Enlarged. P. Blakiston's Son & Co., Philadelphia.

The second edition of this manual appears within three years after the issue of the first edition. The writer regrets in the preface to the present edition that the additions to the text deemed advisable by the progress in bacteriology necessitate a slight increase in the size. The idea has evidently been to keep the book strictly within the limits of what deserves the designation "manual" and this has been quite successfully accomplished. The little work is for its size as complete as could well be desired and yet it is no mere dry collection of facts and principles, but a tempting morsel out of the heart of advancing science. Some of the illustrations do not seem to serve any definite purpose in adding to the value of the book.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Outlines of Anatomy. By Dr. E. W. Holmes. Demi 8vo. 182 pages. Second Edition. New Era Printing Co., Lancaster, Pa.

Lectures on Chemical Pathology in Its Relation to Practical Medicine. By Dr. C. A. Herter. 8vo, 461 pages. Lea Brothers & Co., Philadelphia and New York.

A System of Physiologic Therapeutics. Edited by Dr. S. Solis Cohen. Vol. VI., Dietetics. By Dr. N. S. Davis, Jr. 8vo, 372 pages. P. Blakiston's Son & Co., Philadelphia.

Directions for Class Work in Practical Physiology. By Dr. E. A. Schäfer. 8vo, 76 pages. Illustrated. Longmans, Green & Co., New York, London and Bombay.

SPECIAL ARTICLE.

THE CRAIG COLONY PRIZE ESSAY—SEROTHERAPY IN EPILEPSY.[1]

BY CARLO CENI, M.D.,

OF REGGIO-EMILIO, ITALY;

DOCENT OF NEUROPATHOLOGY IN THE UNIVERSITY OF PAVIA; MEDICAL INTERNE IN THE PSYCHIATRIC INSTITUTE OF REGGIO-EMILIO.

I HAVE availed myself these last years of the rich material offered by our institution for the study of the pathogenesis of idiopathic epilepsy, that I might, with new data, strengthen the autotoxic theory, a theory which is undergoing in neuropathology a larger and larger development. Evans, Régis, Chevalier, Lavaure, Jacobson, Féré, Voisin, D'Abundo, Herter and others agree in admitting that a toxic irritating cause, probably of a biochemical nature and elaborated by the organism, must be of capital import in the determination of the epileptic fit. Unhappily none of the numerous searches for a basis for this theory has afforded a plausible demonstration of the assumed toxic substances, and the different ways that different authors have followed have led to such divergent and contradictory results that we must regard the important question as still unsolved.

I have often endeavored to study this subject in accordance with the views of these different authors, but the results I have obtained, especially in studying the toxicity of urine and blood by means of injection in animals, have convinced me of the great difficulty of this kind of research in which the experimental methods at our disposal are so insufficient and inexact.

Recently I have tried the intra-albuminous injections of epileptic serum (according to Féré's method) into hen's eggs and obtained such convincing results that I flatter myself I have a new and valuable confirmation of the autotoxic theory of epilepsy.[2]

I think we cannot explain by any other interpretation the constant and often remarkable increase of the teratogenic power of the blood serum of epileptics in general, compared with that of healthy individuals, as shown by my researches. Indeed, even if we were to neglect the close relations between the teratogenic and the toxic power of poisons in general, as Féré indicates, we should not know by what other organic phenomenon to explain the remarkable oscillation of the teratogenic power of epileptic blood, other than by the modification of cellular changes, a modification that is admitted for the toxic power.

It is even probable that the circulating toxic principles which have the property of deeply interfering with the normal development of the embryo, either by acting directly on its elements or indirectly through perturbations induced into its annexes,[1] are closely connected with those poisons which, acting as simple irritants upon the formed element, produce the epileptic phenomena.

I have found a series of facts indicating an intimate relation between the degree of the teratogenic power of the blood in epileptics and the importance and nature of the clinical phenomena. This strongly confirms the previous hypothesis. Invariably the teratogenic property of the blood of such patients has always appeared to be in direct relation to the severity of the disease and the date of its beginning. So I feel authorized in entertaining the view that there is a relation between the teratogenic principles and the circulatory toxic ones to which so high an importance is now given in the etiology of epilepsy.

I have demonstrated and strengthened these facts through hundreds of experiments (see preceding note) which have been carried on with great care as to technic, and with the observance of certain rules of my own which I have thought necessary to introduce in the method of intra-albuminous injections.

However, even if the autotoxic theory of epilepsy were not to gain through my researches any step forward, I have referred to them in order to put this question upon a practical ground, although its place in science is not yet so firmly fixed as to be beyond the pale of active discussion.

Now, the belief grows more and more fixed in my mind from the results just referred to that the epileptic phenomena are the consequence, at least for the greater part, of toxic products circulating in the organism. This, together with the encouragement offered by the modern serotherapy, which is grounded upon specific and causal remedies, has led me to ask myself whether in idiopathic epilepsy it would not be possible to discover a similar method of treatment.

Our imperfect notions concerning the pathogenesis of this disease allowed me to proceed only by experiments and most cautiously; therefore I began without preconceived opinions, only being sure that whatever the results might be, even if quite negative, they would still contribute to the pathogenesis of a disease which is still so obscure.

As the blood-serum in epileptics, in my opinion, contains the soluble epileptogenous principles in a quantity varying with the severity of the disease, I tried first to study the effects of small doses of epileptic serum injected into other epileptics. My object,

[1] The Craig Colony Prize for Original Research in Epilepsy is a prize of $200, which has been offered for the past three years by Dr. Frederick Peterson of New York for the best original, unpublished contribution to the pathology and treatment of epilepsy. In 1899 and 1900 the Prize Committee, consisting of three members of the New York Neurological Society, decided that the prize should not be awarded. The committee for the year 1901, consisting of Drs. G. W. Jacoby, Pearce Bailey, and Ira Van Gieson, recommended that the prize be awarded to Dr. Carlo Ceni of Pavia, Italy, for his essay entitled "Serotherapy in Epilepsy." The report of the committee was approved at the meeting of the Board of Managers of Craig Colony, held at Sonyea, N. Y., on October 8, 1901. By the terms of the competition the successful essay became the property of the Colony. In order that it might receive the widest recognition possible, the committee recommended its publication in a general medical journal. In addition to its present appearance in the MEDICAL NEWS it will also appear in the Medical Report of the Colony, soon to be published.

For the year 1901-2 Dr. Peterson renews the prize of $200 for the best original unpublished contribution to the pathology and treatment of epilepsy. Originality is the main condition. All manuscript should be submitted in English. The prize is open to universal competition. Each essay should be anonymous and accompanied by a sealed envelope containing the name and address of the author and bearing upon the outside a motto or device, which is to be inscribed also upon the essay. All papers received will be submitted to a committee, consisting of three members of the New York Neurological Society, and upon the committee's recommendation the award will be made at the annual meeting of the Board of Managers of the Craig Colony, October 14, 1902.

Manuscripts should be sent to Dr. Frederick Peterson, 4 West 50th Street, New York City, on or before September 30, 1902. The successful essay becomes the property of the Craig Colony and will be published in its Medical Report.

[1] Centralblatt f. Nervenheilkunde, Nov., 1899.

founded on the principles of modern serotherapy, was to find out if the specific poison would in time introduce into the organism in which it circulates any property that might be of therapeutic value to other less severe and earlier cases. Such experiments were made upon several patients, but I never obtained any result worth mentioning. I next wished to determine if by progressive doses of the same serum I could render an epileptic more resistant to the dangerous action of the poison that circulates in him. In other words, it was my object to determine the possibility of establishing an immunity, whatever its degree might be, against a poison formed by the organism itself; an immunity such as may be obtained through poisons in general and particularly through poisons of a bacterial origin.

Serotherapy was first applied in mental diseases by Toulouse for alcoholic psychosis (Biological Society of Paris, meeting of March 28, 1896). He administered to dogs large doses of alcohol for a week, in order to excite in their organism the formation of products which would be curative in alcoholic intoxication. The serum of these dogs was injected into a patient suffering with acute alcoholic delirium. The patient was remarked to be sensibly better on the following day. But Toulouse did not express his opinion about an anti-alcoholic serum.

New experiments of serotherapy in mental cases, supposed to be of toxic origin, were afterward announced by Messrs. Mairet and Vires at the Third French Congress of Internal Medicine, which was held at Nancy, August, 1896. These authors injected artificial serum into insane, melancholic and epileptic patients without any beneficial results whatever.

Rabbit-serum and dog-serum were also injected into hysterical, epileptic, maniacal and melancholic subjects. It did not prove beneficial to the hysterical nor to the epileptic. In the others there was improvement in general nutrition. In melancholia there was also some psychic benefit, especially when dog-serum was used. Later Messrs. Mairet and Vires injected two women suffering from severe mania with the serum of a recovered maniac man. One of the cases presented no benefit; in the other a physical and psychic amelioration resulted.

In one of Dr. Bianchi's preliminary notes on serotherapy in phrenosis, which was published almost simultaneously with Toulouse's, Mairet's, and Vire's communication, in the *Riforma Medica* (1896, Vol. III., p. 502), it was stated that in the asylum at Imola, Dr. Brugia was making studies upon serotherapy on the assumption that many perturbations of the mind arise from auto-intoxication. The note was of the following tenor: "Some of the results that have thus far been obtained are brilliant. Recovery has occurred in certain psychopathic cases in which a prognosis of incurability seemed inevitable."

Dr. Brugia did not, however, publish his results, as they proved contradictory. Messrs. Broca, Sapelier and Thiebault, at the meeting of the Academy of Medicine of Paris, December 26, 1899, stated new results favorable to the serotherapy of alcoholism.[1] He experimented with the serum of horses subjected to alcoholic intoxication. This serum has the property of producing a deep disgust for alcoholic beverages.

Mr. D'Abundo, at the Tenth Congress of the Phrenia-tric Society, held in Naples October, 1899, reported some experiments of serotherapy in progressive paralysis. The following is quoted from him: "The blood serum of excited paralytics, in one of the least advanced stages of the disease, proved sedative and restoring." There was a distinct history of syphilis in the patient. I have not yet drawn any conclusion from this, but if the result was not a mere chance I think it militates in defense of an infective-toxic origin of progressive paralysis. We may intuitively perceive that the specific toxicity, which the evolution of the disease in the individual has produced, displays some curative power in initial cases.[1]

Let us now speak of my serotherapeutic experiments in epilepsy, founded upon repeated injections of epileptic serum.

I made my first experiments upon animals and shall confine myself to stating the results. Many intraperitoneal injections of epileptic blood-serum, in increasing doses, were made before I succeeded in injecting with impunity, into cavities, doses of twice the strength of the original fatal dose. The animals that first presented a severe hypothermy and weakness in time not only suffered no ill effect from the treatment, but they increased steadily in weight. The way seemed to be opened for a therapeutic experiment in epilepsy. It seemed possible to benefit epileptics by lessening their cellular sensibility through a repeated and progressive contact with the presumed toxic epileptogenic substances. Two procedures were possible; one, the injecting of blood-serum of one epileptic into a second epileptic less ill than the first; the other, the re-injecting into an epileptic of the blood-serum drawn from him after bleeding.

These two methods, apparently so different, should give the same results. In both cases, admitting that the blood contains the toxic and soluble principles believed to produce the epileptic phenomena, there is artificially introduced into the organism a much greater quantity of these poisons than is usually found there.

My hypothesis may be made clearer by referring briefly to my explanation of the mechanism by which epileptic crises take place. As stated in a previous note on the pathogenesis of epilepsy, the crises are only brought about by a discharge of dynamic energy gathered in epileptogenic centers in consequence of an irritation which is lasting, constant and uniform for an indeterminate period of time. I drew this interpretation only from the evidence furnished by my researches, to the effect that the amount of poison circulating in epileptic blood does not change in the same individual in different stages of the disease. My hypothesis, which forms the basis of the present experimental researches, differs from the views held by most adherents of the autotoxic theory. According to these latter the intermittency of epileptic seizures depends upon an excessive periodical irritation of the nervous centers which is caused by a periodical production or by an accumulation of toxic principles, anomalous to the organism. With such an interpretation it would have been difficult to foresee the possibility of immunizing against the poisons circulating in the organism by periodical injections of the same poisons, even if made in progressive doses.

A brief exposition of some of the new therapeutic experiments that I have been making for more than two years past in our Institute, always with very encouraging results, is the object of the present communication. I shall first, however, briefly describe the technics used.

First, I must emphasize the necessity of scrupulously following the rules of asepsis and antisepsis in every step of the procedure, namely, in blood-letting, in the separation and preservation of the serum, and in the injections. The condition of the patient who is to furnish the blood must be ascertained, in order that the danger of transmitting disease be avoided. As to blood-letting, I use tubular needles of large bore fixed

[1] Scalia-Terapia delle Malattie Mentali, p. 227.

[1] Annali di Neurologia, Anno XVII., Fasc. 4.

on a glass pipette about 10 centimeters long. With this simple instrument and a recipient with a large opening (I use Erlenmeyer's bottles), we can draw aseptically as much blood as we like, without exposing it to the contact of air. The tubular needle is inserted into a venous trunk that has been compressed above. The free end of the pipette is introduced into the aforementioned receptacle. After having again disinfected the slight wound and washed it with alcohol and ether, it is closed with a drop of liquid taffetas. In this way a patient can be bled several times without suffering the least inconvenience. The quantity of blood withdrawn varies with the individual. The most I have taken at one time from strong persons is 250 to 300 cubic centimeters. Then I separate the serum and divide it in small bottles holding 10 cubic centimeters each, only adding some camphor. However, that the preservation may be surer, I have long used fractional sterilization. If this be done at low temperatures it has no influence on the beneficial properties of the serum.

Both in injecting serum from one epileptic into another and in reinjecting into the same patient I always follow the method of progressive doses, beginning with 3 to 5 cubic centimeters and increasing gradually up to 10 or 20 cubic centimeters in thirty or forty days. As will be seen from the histories of the different cases, this method is necessary from the fact that some patients react violently to the first injections even when made in small doses, and present the symptoms of an acute intoxication, which may even be dangerous. This is the crisis of adaptation and is quite transitory, disappearing after a few injections. Commonly several injections, continued for some weeks, are necessary before durable results are obtained.

My method of treatment is briefly as follows: During the first month I inject into the glutei, at intervals of a few days and in progressive doses, a total quantity of 40 or 50 cubic centimeters. During the following months, when I think the patient has overcome the first adjusting period, I carry the total dose up to 80, 90 or 100 cubic centimeters, especially when the patient begins to improve. In these cases I have continued the injections until I thought the maximum advantages had been obtained. This I inferred from the presence of a firm equilibrium in the general condition as shown by their no longer reacting, but being indifferent to the treatment.

I think, however, that an exact general rule for these injections cannot yet be given. It always depends upon the peculiar conditions of the individual into whom the injections are to be made. We shall see that these conditions may be such as to contra-indicate treatment altogether.

Ten epileptics have thus far been subjected to the injections. They have been under my observation during a period varying from one to two years. The final results, therefore, may be considered as of a scientific and practical value, upon which we may justly rely in our inferences and judgment. All the cases exhibited the severest form of idiopathic epilepsy, both as to the number and intensity of the motor crises, and as to the presence of psychic and sensorial phenomena.

Case I.—C. A., a marriageable, strongly-constituted young woman, twenty-two years of age, by trade a dressmaker. She has no hereditary precedents. About eight years ago she began to suffer from intense headaches and insomnia, and soon afterward from swoons (two or three a week) with unconsciousness. About this time serious gastric perturbations began also to be evident and the patient suffers continually from heaviness in the epigastrium, and is not seldom tormented with real gastralgias that last many hours and even days. Her tongue is dry and always covered with a whitish coating. She vomits and raises wind, particularly a few hours after her meals. The swoons have ceased for nearly four years, giving way to tonic and clonic convulsive spasms which grew more and more severe, particularly at the time of her menstrual periods. It is usually an abrupt, cryless spasm characterized particularly by the violence of the general muscular shocks that succeed the tonic period. It lasts from ten to fifteen minutes. Then the patient becomes unconscious for two hours or more. She soon grew disinclined, tiresome and very irascible. These last two years in which the spasms followed each other with extraordinary frequency (five to fifteen times in twenty-four hours), she has become disorderly, spiteful and often violent and aggressive.

Since the patient grew worse her menses have ceased; the gastric perturbations seem to get worse. Besides, one year ago a dry erythema on a deep-red ground appeared on the skin of the breast and abdomen and particularly of the internal parts of the thighs and of the anterior parts of the legs as far as the instep. This produces a constant and intense smarting especially during the night, so that the patient often cannot sleep.

For several years we gave her strong doses of bromide (8 to 10 grams a day) and 4 grams of chloral every night for the insomnia. We tried also to conquer the skin erythema by various internal and external remedies, but always in vain.

At present the patient always sits aside, distant from her companions, silent and down-cast. Her eye is grim and without expression; her face wrinkled, frowning and cyanotic. Her dilated pupils react very poorly to light. Her cutaneous and tendinous reflexes are rather weak, and standing upright with joined feet and closed eyes makes her giddy. A remarkable torpor is to be seen in her motor and psychomotor manifestations. On the first of August the patient weighed 63 kilograms. Her pulse was weak and slow. We experimented on this subject with the serum taken from the blood of an epileptic who was in a no less severe condition, and had been confined in our institution for many years. On the first days of August, 1899, we began to inject small doses of the said serum, but at the third injection of 5 cubic centimeters made at an interval of two days from the last, we suspended treatment as the patient became suddenly worse. The epileptic convulsions became more intense and the patient fell into a state of drowsiness and semi-unconsciousness. She looked more imbecile and cyanotic than ever; the sensibility had grown more obtuse; the reflexes were weaker and the pupils more rigid. She constantly dosed, and when awake she could hardly stand erect. She paid no attention to questions and presented a remarkable torpor in all psychic manifestations.

She remained in this condition for about five days from the last injection. Meanwhile she became sensibly worse. Toward the middle of the said month her weight had gone down to 61.800 kilograms. We let her alone until the beginning of September, when she had returned to about her original condition. Then we resumed the injections with the serum drawn from the same subject as before, and not only are they now borne, even in larger doses, without inconvenience, but they prove also very beneficial to the patient herself. By the end of September we had injected, with several intervals, a total quantity of 50 cubic centimeters of serum. The number of the convulsive spasms in this month decreased to less than half that of the preceding months. Besides, the fits are less severe, much shorter than previously, and quite deprived of muscular shocks.

Sometimes they are limited to a mere unconsciousness lasting a few seconds and being attended by a rapid tonic contraction of a limited group of the muscles of the body.

The muscles of the neck, now on the right side, now on the left, present particularly these contractions. The patient's general condition is also better; her appearance is livelier and more expressive; she appears no longer frowning and cyanotic, and her behavior is more orderly. She grows more docile and less irascible and begins to speak with her companions.

The sensibility and general reflexes may be considered normal, and the pupils react well to light. Her menses, however, have not appeared. Although the gastric disturbances and the skin erythema still persist, they are remarkably abated. The gastralgias have almost disappeared and the patient feels now, only transitorily, a sense of heaviness in the epigastrium, which formerly was almost continual. The tongue is no longer so foul and the eructations are rather fewer. The erythema has grown more and more limited, its characteristic aspect disappears little by little from the margin to the center, giving way to mere irregular spots of a reddish color. The intense smarting characterizing this cutaneous disease diminishes very much and the patient complains only of a local itching, especially at the points where the erythema is in process of recovery.

During the last fortnight of September the patient began to sleep during the night, so that toward the end of the month the chloral was discontinued. Her pulse became normal. Her weight is now 64.300 kilograms.

In October she received a total of 60 cubic centimeters of serum and by degrees she made remarkable improvement. During this month the spasms were reduced to six, three of which were only rapid giddinesses without complete unconsciousness.

She is now a healthy-looking, mild, orderly girl and she seeks elegance in her dress. She embroiders during the day, likes to converse with her companions and sleeps well at night. She complains of but slight gastric disturbances, which are limited to some eructations, occurring on the days of the epileptic crises. All sensation of heaviness in the epigastrium has disappeared and the tongue is always clean and rosy. The cutaneous erythema may be said to have disappeared and in its place only irregular rosy spots remain. The menses appeared this month for the first time in a year and they present a regular course. The patient weighs 65.200 kilograms.

November: In three doses a total of 70 cubic centimeters of serum are injected and the dose of bromide is reduced to 4 grams a day. During the entire month only four epileptic seizures occurred, and even these almost always during the twenty-four hours preceding the appearance of the menses. The gastric disturbances have disappeared and no trace of the erythema remains. The skin has grown everywhere soft, normal, clear and fresh. Weight 66.500 kilograms.

December: During this month only one injection of 20 cubic centimeters of serum was made and the patient continued well without any incident until the 15th. In the evening of that day two new convulsive fits and a giddiness took place. These were the result of the total suspension of the bromide treatment ordered on the preceding day. The patient soon became as well as at first, but the bromide treatment was continued on the following day in doses of 3 grams a day. Her menses are regular, even after a few epileptic crises. During this month the total number of convulsions and attacks of giddiness was seven. She weighs 66.800 kilograms.

January, 1900: Two injections of 20 cubic centimeters each were made. The condition of the patient remains unchanged. During this month only four fits occurred, and these before the menses appeared. Her weight has increased to 67.500 kilograms.

February: The injections are suspended and the patient continues well with a very small number of fits. Her weight is 66.500 kilograms.

March: The suspensions of the serum injections is continued, but the condition of the patient and the number of the fits are almost the same as during the preceding months. Her weight is 66.200 kilograms.

In the beginning of April, insistently urged by her family, she was dismissed from the institution.

December, 1899	3	4	66.800
January, 1900	3	1	67.500
February, 1900	4	2	66.500
March, 1900	3	4	66.200

According to information received from the physician of the patient's family, in May, 1900, the fits increased again, but only transitorily, for they diminished again during the following month. Toward the end of 1900, that is, about one year after the treatment, the motor crises increased again in number and severity. The average monthly rate of these crises, however, never reached a third of the number the patient presented before she underwent the serotherapy. Her physical and mental condition always remained good and allowed her to take care of her house, whilst formerly they not only hindered her from it, but had often caused her to be confined in our institution.

Case II.—R. Paul, twenty-two years of age, is a young man of strong constitution, sober, rather defective in intelligence and of a shrinking, timid nature. Serious hereditary antecedents are found in his paternal line. He began four years ago to be subject to giddiness, of an epileptic character, with unconsciousness. These attacks of vertigo, that commonly last a few minutes, were rare at first (one or two weekly); but they grew more and more frequent, so that they appeared during the past two years from three to five times a day.

Two years ago the first complete epileptic fit appeared, and subsequently the fits have reappeared at intervals of from twenty to thirty days. Yet for the past year, during these long inter-paroxysmal periods, the attacks of giddiness have been more frequent than formerly, occurring from five to ten times a day. These attacks, moreover, are attended with hallucinations. The psychic phenomena are quite transitory and last only a few minutes. At their subsidence the patient quickly becomes normal. During the past few months, in which there has also been an increase of the convulsive fits, the patient has had periods of unusual restlessness, with a slight torpor of the intellectual powers. These periods last from a few hours to whole days. The patient now suffers from want of sleep and complains constantly of a sense of heaviness in the head. His nutrition has deteriorated and he has grown depressed, irascible and sullen. No disturbance of sensibility or motility. General reflexes normal. For the past year the patient has been taking

bromide in large doses. Toward the end of August 1899, he weighed 68.300 kilograms.

In the first days of September, 1899, the patient undergoes a regular treatment of injections with the blood-serum drawn from another patient suffering from a more severe type of epilepsy. In this month a total of 40 cubic centimeters of serum are injected in small doses. During the first fortnight of the treatment the patient appeared to get rather worse and lost about 2 kilograms in weight. The convulsive fits are more numerous, so that they appear almost every day and the sense of heaviness in the head has now become a strong and almost constant cephalalgia. The patient is more restless and depressed than ever, and often refuses to eat. In the second half of the month this state of things disappears by degrees. The patient gets back into the condition of the preceding months and even shows signs of improvement. His weight has increased to 67.600 kilograms.

October: In this month a total of 60 cubic centimeters of serum is injected and at the beginning of the month the bromide treatment is entirely suspended. The patient soon passes into a state of unusual well-being. He sleeps quietly all night. The cephalalgia and the sense of heaviness in the head, as well as the hallucinations, disappeared. In the whole month there are but one convulsive fit and three attacks of giddiness. The patient weighs 71.300 kilograms.

November: The patient receives 55 cubic centimeters of serum and is perfectly well until the 27th. On that day two fits occur with short interval. On the following day he suffers from an attack of giddiness and then resumes his normal condition. The weight is 72 kilograms.

December: In this month 30 cubic centimeters are injected and the condition of the patient remains almost as it was in the preceding month. The period of complete pause without psychic or motor epileptic phenomena lasts throughout the month, to the great wonder and joy of the patient. He looks more florid than usual; his physiognomy is lively and he is good-humored, gay and of a mild, good temper. His weight has reached 73.200 kilograms.

January, 1900: The serum injections are suspended this month and the bromide treatment continues also to be suspended. The condition of the patient remains almost unvaried; but the fits reappeared after an interval of 50 days. He had a series of four attacks of giddiness and a convulsive fit in a few hours, which caused him to be dejected and sad for two days. His weight goes down to 71.600 kilograms.

February: Both the serum injections and the bromide treatment are still interrupted. The patient continues well without any disturbance until the end of the month, namely, for 40 consecutive days. He then has a series of three convulsions. This new crisis is followed by a short period of depression. His weight goes down to 69.600 kilograms.

March: Injections are resumed and in this month 45 cubic centimeters of serum are injected. The patient rapidly improves and continues well until the end of the month. Then a new series of three convulsive fits appear from which he makes a rapid recovery. The weight increases to 73.400 kilograms.

April: In the first half of the month two serum injections of 15 cubic centimeters each are made. His general condition remains unaltered, and toward the end of the month he is dismissed at the imperative request of his family. At the time of his dismissal the patient weighed 74.500 kilograms; that is, his weight had increased 6.200 kilograms since the day the injections were begun.

March, 1900.....	3	—	73.400
April, 1900.....	2	1	74.500

According to the reports received from the family, the patient's condition, in the following months of April, May, June and July, remained unchanged from what it was when he was discharged. In the month of August, that is, about one year after the treatment, the epileptic crises began to increase, especially in the form of vertigoes. At the same time the weight decreased, being since that time about 70 kilograms. The physical phenomena, however, that formerly had necessitated the segregation of this epileptic from society, have not yet reappeared, although the bromide which he took in large doses before the treatment has not been resumed.

Case III.—C. Alfred, a countryman, thirty-two years old, unmarried. His mother and father suffered from pellagra with severe nervous phenomena. The patient has always been strong, taciturn and of limited intelligence. From boyhood he suffered from epilepsy, and when about twenty he began to be taken with caphalalgia and insomnia and became stubborn. Then he grew very disorderly and restless, and the epileptic fits having rapidly increased in number, he soon entered into a state of great psychical confusion with periods of psychomotor unrest, interrupted by hallucinatory disturbances.

During the seven years he remained in our institution, although high doses of bromide were daily administered, he grew progressively worse; the epileptic fits became more frequent and of late years they have occurred with an average of thirty to forty a month. Severe psychic disturbances with periods of great agitation, lasting a few hours or even days, became frequent. The state of mental confusion is constant, and pronounced loss of memory is marked. The convulsive fit is severe and is preceded by a cry.

The general sensibility is obtuse; the cutaneous and tendon reflexes are weak. The pupils are equal, commonly dilated and react feebly to light. Standing upright with joined feet and closed eyes causes giddiness. The patient in his general movements presents a remarkable torpor. The weight at the end of October, 1899, is 75.800 kilograms.

With this patient we try the action of the blood-serum he himself has furnished, after having been bled. In the first days of the month of November the injections are begun. Made in high doses of 10 cubic centimeters, they are soon increased to 20 cubic centimeters. The patient presents no disturbance at all. Thus in his first month of treatment a total quantity of 80 cubic centimeters of serum is injected.

Toward the end of the month he appears to be getting better. The epileptic phenomena, both motor and psychic, have limited themselves in number and intensity. The convulsive fit that commonly lasted about a quarter of an hour now lasts but from two to four minutes. The psychic equivalents which were almost daily in the preceding months appear but three times this month. They take the form of a brief agitation.

Still the great psychic and motor torpor persists, and the patient always presents Romberg's phenomenon. No considerable modification appears in sensibility or in the general reflexes. The general aspect of the patient seems to be rather better and his weight increases to 77.300 kilograms.

December, 1899: In this month 90 cubic centimeters of his serum are injected. Improvement is rapid. The epileptic motor crises are reduced to three during the month. They appear after twenty-eight days of complete pause, and twice the fit is not followed by the muscular shocks. The hallucinations and the psychic equivalents have disappeared, and the patient presents now a remarkable rousing from the state of general torpor and mental confusion, in which he has been for several years. His physiognomy has a livelier expression; he pays attention to questions and to what happens around him; he can give correct answers and recollects some occurrences of the last few weeks. He is quiet and helps willingly with the simple work of the ward. His countenance is florid with a bright skin and a healthy color, and he is more active in his movements. Romberg's phenomenon has disappeared; the sensibility is less obtuse; the reflexes have now become rather exaggerated and the pupils react promptly to light. He now weighs 81.600 kilograms, an increase of more than 6 kilograms in two months.

January, 1900: The total quantity of serum injected is 110 cubic centimeters. The general condition continues better, although in this month there is a slight increase of the epileptic crises. There is only one complete epileptic fit, but there are eight very slight fits. These latter are limited to a mere swooning or to a rapid increase of muscular tonicity. No psychic or psychosensorial disturbance; nay, we may say that the state of torpor in the psychic and motor activities, so long characteristic in the patient, has almost entirely disappeared. Even the affective sentiments are aroused, and more particularly the religious ones. The patient weighs 82.500 kilograms.

February: The serum injections are suspended. Both the physical and the psychical conditions of the patient remain about the same. The number of epileptic crises is almost the same as in the preceding month, but with the difference that they are more intense. Indeed, the complete fits with muscular shocks in this month amount to three. The weight is 82.100 kilograms.

March: The serum injections are still suspended. The favorable condition of nutrition is unvaried. The patient weighs 82 kilograms.

April: In this month two injections of 20 cubic centimeters each are made. No remarkable variation is observed in the psychic state of the patient. The epileptic attacks present no modification either in number or intensity. The weight again undergoes a slight increase, reaching 82.500 kilograms.

May and June: There is no change in the patient's condition, although the injections have been again interrupted during all this period.

During continued suspension of the treatment, the general condition of the patient began to grow worse. This phase lasted four months, that is, until the end of November. During this time the convulsions occurred nine times a month. The weight decreased to 79 kilograms.

In November, 1900, the patient had a second and progressive relapse. The fits increased by about one a month, so that in May, 1901, he had 17 of them. The nutritive state of the patient also grew worse, so that the last monthly average was 77.500 kilograms.

In this period of progressive failure the psychosensorial phenomena also appeared again, but were less frequent than formerly. Therefore, we may say that the patient, more than one year after the suspension of the injections, had not descended so low as he was before the beginning of treatment. This also appears from the number of the crises and from the weight of the body as shown in the diary.

Case IV.—Alfred V., a workman, thirty-two years of age, unmarried, of a strong constitution and without hereditary precedents. When fourteen years old, in sequence to a fright, he had the first epileptic fit. Then the fits began to appear at very short intervals so that they soon occurred two or three times in twenty-four hours. They were chiefly nocturnal. In the last three years, however, the fits increased in intensity. They showed a cumulative tendency, coming three or four times a day with three to five days' interval. The attack is sudden, violent and without cry.

The patient becomes pale, falls, and after a tonic period of two or three minutes presents general and intense muscular shocks which last about eight minutes. After these crises the patient enters into a state of deep mental confusion, which may last several hours. Then he suffers from a severe cephalalgia which generally continues for all the following day. For some years past he has suffered from insomnia, and lately he has become physically weak. His weight, verified at the end of October, 1899, is 70 kilograms. The patient is of a quiet, good disposition and fairly intelligent. In the intermission, when he has overcome the confusion and cephalalgia consequent upon the fits, his general condition is that of a healthy man. There is nothing worthy of mention regarding sensibility or general reflexes. For the past year he has taken 4 grams of bromide every day.

November, 1899: The treatment by injections is begun. In this case, also, we used the blood-serum of the patient, previously taken from his own veins. In the first month a total of 60 cubic centimeters of the serum was injected. The patient tolerates these injections without any disturbance. His general condition remains unchanged for the first twenty days. In the last ten days of the month we note some amelioration in the epileptic phenomena. The fits during these days do not follow each other in series as before, but are isolated, coming at periods of five days. Moreover, the attacks become shorter and less intense, lasting two or

three minutes. After these last fits the patient returns directly to his normal condition without suffering from the confusion and headache that for so long troubled him. He now seems also physically better and weighs 72.600 kilograms. He continues to sleep poorly.

December: The total quantity of serum injected is 70 cubic centimeters and there are no attacks. The patient feels a sense of easiness quite unusual. He now sleeps quietly at night and passes the day in reading. His general appearance has become much better; his color is healthy, his expression bright and he weighs 75.800 kilograms.

January, 1900: The total quantity of serum injected in this month is 60 cubic centimeters, and the daily dose of bromide is now brought down from 4 grams to 2 grams. The patient continues in general good health. Two fits occur in this month, but they are short and much less severe than was the first one, consisting only of a short period of unconsciousness with an increased degree of muscular tonicity. The weight remains 75.700 kilograms.

February: The total quantity of serum injected is 70 cubic centimeters. The fits are more frequent, coming at intervals of 8 or 10 days, but they are always isolated and much less intense than before. The muscular fits are but two in all the month. There is no psychic disturbance and the weight is 75.300 kilograms.

March and April: In these two months the serum injections are suspended and the patient continues in those conditions of amelioration he has reached through the treatment. The fits are always isolated as in the preceding months; some of them are still accompanied by muscular shocks, but the greater number are mere swoons. The weight of the patient during the month of March was 75 and in April 74.500 kilograms.

May: Twenty cubic centimeters of serum are injected. The general condition of the patient continues good. In all the month there are but two convulsive fits and one giddiness. The weight goes up to 76.300 kilograms.

June: The serum-injections are definitely suspended. The general state of the patient remains the same. The fits are infrequent. The weight is 76 kilograms.

From that time on, to May, 1901, the general condition of the patient remained in a state of stable equilibrium during which the motor crises come only with an average rate of twice or three times a month, and no longer caused the severe phenomena which were constant before treatment was begun.

The nutritional state of the patient is excellent. The weight, although the injections have been suspended for more than a year, is constantly, by some kilograms, greater than before the treatment.

Case V.—R. Pius, an unmarried man, fifty-two years old, of strong constitution. The first epileptic symptoms appeared twenty years ago, following a fright. The patient soon began to have convulsive fits, occurring first with an interval of from five to six months, but which rapidly became more frequent, until they occurred every two or three days. For the past two years the fits are very frequent and are repeated two, three and even four times in the same day. They have a cumulative tendency. After these series of fits, periods of pause of two or three days follow. The convulsive fit is sudden and is preceded by a loud cry. The tonic state is usualy short, whilst the clonic state, which is always general, lasts about ten or fifteen minutes. The violent muscular shocks are followed by coma, which lasts about half an hour. When this disappears the patient goes into a state of deep general torpor that may last several hours. During this last stage he mutters to himself and has hallucinations of sight and hearing.

The intelligence has shown a remarkable and progressive decay, and at present both the psychic and motor phenomena are so defective that the patient cannot care for himself. The patient is completely unconscious of place and time; he remembers nothing, not even his own name; his face is cyanotic and his countenance stupid; he can hardly stand upright; he presents the Romberg symptom even when the eyes are open; and he walks so uncertainly and totteringly that he often has to be supported. During the past few months he passes the days sitting and the sleepless nights grumbling. He often voids urine and feces involuntarily. At present his sensibility is very obtuse; the cutaneous and tendinous reflexes are remarkably weak; the pupils are unequal and react to light very slowly; the tongue is always thickly coated. He has frequent eructations, and his breath has a penetrating acetone odor. He is getting progressively worse. Eight grams was the daily dose of potassium bromide administered during the two years he had been in the institution.

The method chosen for this patient was the re-injection of his own serum. In the beginning of February, 1900, 300 cubic centimeters of his blood were withdrawn, and on the 15th of the same month we began the treatment by injection. From this day until the end of March we injected a total quantity of 80 cubic centimeters of the said serum.

In the first half of March we noted general psychic and physical amelioration, which in the following days became sufficiently remarkable to attract the attention of the persons employed in the institution.

The fits are lessened in intensity and in number. Sometimes they are now limited to the cry and to a slight increase of muscular tonicity, without any shock. The complete fits, that alternate with the above said modification, in the month of March are reduced to about half the number of the preceding months. The patient presents at the same time a remarkable improvement in his psychical condition; his physiognomy grows livelier and more expressive; and the hallucinations after the fits, formerly so frequent, have disappeared. The patient now pays attention to questions and begins to interest himself in what happens around him. It is wonderful to see the progressive awakening

of his consciousness. He knows the place where he lives; he begins to have some idea, though confused, of his condition and can recollect well enough some facts that happened before he entered the asylum. He does not remember at all what has happened in the two years since he entered the institution, but he recollects well enough the occurrences of the month of March, the time of the first injections. He has become careful in his dress and for a month he has not been filthy. The general sensibility is less obtuse than before, and is almost normal. The cutaneous reflexes are still weak, while the tendon reflexes have now become more active. The pupils, which once were unequal and reacted feebly to light, now are equal and react well. The Romberg symptom is no longer present and the gait is normal. Physically, also, he is much better. The skin of the face is no longer cyanotic and wrinkled, but florid and bright; the tongue no longer whitish and foul, but clean and rosy; the breath no longer bad, and the eructations much lessened. He now sleeps quietly the whole night. His weight is 71.600 kilograms, that is, a gain of 6 kilograms in forty-five days.

April: In this month 60 cubic centimeters of serum are injected. The bromide is reduced from 10 grams a day to 2 grams. The epileptic crises are now much less numerous, and the general improvement, though slow, is always progressive. The patient now looks like a healthy man. He is conscious of his condition and appears good-humored and good-tempered. He likes to jest with his companions. He can form judgments fairly well, and the activity of his ideas, though limited, is ready. Although his conversation is defective in some respects, it is in general remarkably coherent. His sentiments of affection are also more in evidence. He interests himself about his family; he wishes to see them and often expresses the wish to be dismissed. His weight is 73.700 kilograms.

May: The serum injections are suspended, but the treatment of 2 grams of bromide every day is continued. As is seen from the diary, the epileptic crises present an inconsiderable increase in number, but their intensity is notably increased. After two severe convulsive fits, following each other at an interval of about two hours, the patient enters again into a state of great mental confusion and exhibits at the same time hallucinatory phenomena. Although he gets worse, he is not in as bad a condition as he was before he underwent the injections. The relapse is transitory and disappears after a period of about three days.

June: Injections are begun again and during the month 32 cubic centimeters of serum are injected. The general condition of the patient quickly improves. His weight reaches 75.500 kilograms. However, the fits are a little more numerous, though not very intense.

July: In this month the serum injections are suspended again and now quite definitely. However, the general condition of the patient continues to improve so that in the following September his weight attains an average of 77.600 kilograms, an increase of about 13 kilograms. During this period the convulsions recur on an average of four or five times a month. The hallucinatory phenomena with severe mental confusion that first reappeared in May come again, but only for one day.

October: In this month, and especially in the ensuing November and December, a slight relapse occurs. The motor crises increase to six a month. The weight decreases first to 75, then to 73 and then to 72.400 kilograms. The hallucinatory crises are present three times in these months, but they are always transitory and short.

From January, 1901, to May, 1901, the general state of the patient is practically unvaried. The fits always occur about six times a month, and the weight stays about 72.500 kilograms. The mental state remains fair. The psychosensorial crises grow a little more numerous in comparison with the preceding months.

Case VI.—G. Armida, a young girl, twelve years of age, without hereditary disease. The patient was well until ten years of age. She had had a normal physical and psychic development and had shown no sign of anomalies in character. Then, without any determined cause, she suddenly began to have epileptic convulsions which were very intense from the beginning. These became more frequent, so that during the past year they came fifty or more times a month. The fits are usually isolated and are both nocturnal and diurnal. Sometimes they come in series of three or four. They last about ten minutes, are attended with involuntary discharge of urine, and are followed by intense headache, lasting several hours.

Since the appearance of these crises the patient has greatly changed. She has grown very restless, disorderly and disobedient, becoming almost intolerable by reason of her spiteful and irascible temper. She has impulsive tendencies and a mania to steal. Her intelligence is very limited. Although she was for a time in the first class of the elementary school when seven or eight years of age, she does not even know the alphabet. Her sentiments of affection are very rudimentary. She does not pay attention to questions and she cares little for reproofs. She often utters silly and senseless words and laughs easily in an immoderate and foolish manner. She is very restless, always dancing and jumping, and trying to rush upon her neighbors to tear their hair and dresses. There are no paralytic disturbances. The sensibility to pain is rather diminished. The pupils are equal and react well to light. The tendon reflexes are exaggerated. The pulse is very slow. At the end of February, 1900, she weighs 34.600 kilograms.

In the beginning of March the patient receives injections of the blood-serum drawn from another less severely affected epileptic. During the month a total of 40 cubic centimeters is injected. Soon after the first injections a progressive amelioration is to be seen in her general condition. In the first fortnight the weight increases more than 3 kilograms and at the end of the month reaches 42.300 kilograms. There is also a remarkable change in character and tendencies; she grows by degrees less stubborn and irascible, and more orderly and obedient. The convulsive attacks are also greatly reduced in number and intensity. In the whole month the crises are reduced to nine, some of which are mere "absences." The nocturnal convulsions were the first to disappear.

In April 60 cubic centimeters of serum are injected. The patient continues to get progressively better. The facial expression has improved, in that stupidity is being replaced by intelligence. The impulsive tendencies have disappeared and she has grown very orderly, good and even-tempered. She is obedient and willing to work. The intellectual powers also present considerable amelioration. The patient answers reasonably to questions, remembers the time when she was tormented by numerous fits and wants to be sent back to her parents. The general reflexes and sensibility are normal, the pulse is regular. The weight has increased to 48.300 kilograms; an increase of about 14 kilograms. No epileptic crises this month.

May: A total of 45 cubic centimeters of serum is injected. The patient has no epileptic crises. She is always good, gentle and obliging. The weight has now reached 49.200 kilograms.

June: A total injection of 30 cubic centimeters of serum. There is no epileptic crisis and the good condition of the patient remains unvaried. Whereas, for a long time the girl has been taking a daily dose of 6 grams of bromide, by a slow and progressive diminution of the dose, the drug is now completely suspended. The weight is 50.100 kilograms, that is, an increase of 16 kilograms in five months. On the 15th of this month her menses appear for the first time. They are abundant and last for three days.

July: The serum injections are entirely suspended. The girl continues in excellent general health. Her menses come in this month again and from this time they continue regularly. She has no epileptic phenomena. The girl has undergone complete transformation in physiognomy and character; she looks like a normal, intelligent person; she grows better, milder and more active. In this month she begins to go to the institution school, where she soon distinguishes herself by her diligence and progress. In a short time she learns to read and write. She behaves well to every one. In dress she is modest, but rather elegant.

From January, 1901, until the present writing the weight of the girl remains almost unvaried, but in other ways she is constantly improving.

March: She is no longer to be regarded as the brutish creature she was before the treatment. She is a fine, healthy girl, with correct manners. She dresses carefully and with elegance. She is thirteen, but appears to be at least sixteen.

Toward the end of May she is released from the institution and returns to her family, where she employs herself with domestic duties, helping her parents as a healthy person.

Case VII.—Charles M., forty-five years old, a bookkeeper, has been in our hospital sixteen years. His mother was hysterical and his father died of progressive paralysis. Since early childhood the patient presented epileptic symptoms under the form of a sudden waking in the night with loud cries and passage of urine. From infancy he was eccentric, irascible and obstinate. Soon intense convulsive fits began to appear, at first only by night, then by day. They were limited to four or five a month. The epileptic crises grew more frequent, taking the form of vertigoes, always with loud warning cries.

When twenty-five years old he married and soon afterward severe psychic and psychosensorial disturbances appeared in the form of maniacal excitement with hallucinations of sight and hearing. Commitment to this institution was soon necessary. In the first years the disease had several periods of intermission. He was frequently committed here and then released. In 1885 he entered definitely, for the severe psychic disturbances had assumed a lasting character and his intellectual powers had grown much weaker.

Although the bromide treatment was continual and in high doses, he became progressively worse. For ten years the epileptic crises, in the form of convulsive fits and vertigoes, were repeated with remarkable frequency, occurring from three to five times in the twenty-four hours. In the past three years, however, these crises have notably lessened in number, and recently they have been reduced to four or five a week, the giddinesses being in the majority. The patient has usually one, two or even more periods of excitement each month, which last two or three days. During this time he is confused, disorderly, very irritable, and sometimes violent. The patient is becoming demented, as is shown by his difficulty of expression, his lack of perception, his deficiency of association, his absolute want of affective sentiments and by his failure of memory. The pupils are equal, but scarcely react to light. The cutaneous and tendon reflexes are diminished. Standing upright, even with open eyes, makes him dizzy. The sensibility in general is obtuse, but there is nothing remarkable in the special senses. The general nutrition is always fairly good. The weight is about 75 kilograms.

In January, 1900, the patient was bled abundantly, for the auto-serotherapy was to be tried in this case.

In February 60 cubic centimeters of the serum are injected at different times. The bromide treatment, on account of the extraordinary severity of the case, was continued. The patient does not react acutely, but gets slowly and progressively worse. He is moodier than ever, and in the second half of the month he grows still more fretful and confused. He suffers from continual anorexia and has persecutory ideas. The convulsive fits and the vertigoes are increased in number and the weight diminishes about 2 kilograms.

March: In this month only 50 cubic centimeters are reinjected. The patient grows worse and worse. The epileptic crises have again become more numerous and the patient has two attacks of mental confusion and irritability, during which he is very disorderly and impulsive. These two attacks last three days each. In the intervals the general reflexes, which in the preceding months had diminished, augment. The weight goes down to 71.500 kilograms.

April: Auto-serotherapy is abandoned.

On the 15th of May the injections are resumed, but now with the blood-serum drawn from another epileptic. During the time when no injections at all were given, the patient seemed somewhat improved. No psychic phenomenon worth mentioning appeared in the forty-five days.

On the 15th of June, after total injections of 35 cubic centimeters of serum, we suspend this new treatment also, as it, too, was unsuccessful. The patient grew worse; he suffered from obstinate headache and from mental confusion stronger than ever, attended with excitement. Even the motor crises and the attacks of vertigo took place more frequently, and the general nutritive conditions were worse again. The weight at the end of June was about 68.800 kilograms.

In spite of the definitive suspension of the injections the patient, instead of recovering his habitual state, falls in the following months, *i.e.*, from July until the end of November, into a state of constant mental confusion with serious psychic phenomena, and an increase of the motor crises, which in this period come about fifty times a month.

In December and January, 1901, the patient began, little by little, to get better. The motor crises and the vertigoes lessened every month. His physical improvement was steady, and the psychic phenomena, especially the great mental confusion, grew less intense. At the end of one year and a half, then, he was in the same condition as he was before he underwent the injections.

Case VIII.—Albertina Bus, twelve years old, of a delicate physical constitution. Her mother's parents are neuropathic. The girl seems to have reached the age of nine years in normal physical condition, and without suffering from any disease. Being very quick and intelligent she went early to school, where for her talents and good character she often won the praise of her teachers.

Three years ago the girl had typhoid fever. On recovering she had for a few days abundant and frequent epistaxis. She then developed convulsive fits of an epileptic character, which from the first were both intense and long. The fits came either suddenly or with a little warning cry. She always lost consciousness, and was dull and confused for some hours afterward, and often the attack was followed by a severe cephalalgia, which lasted the greater part of the day. During the fit she frequently voided urine involuntarily.

For some months the fits occurred once or twice a week, but then they became exceedingly numerous, so that in the past fifteen months they occurred from five to seven times or more in the twenty-four hours. They were always intense and complete, with violent muscular shocks. They came more frequently by day than by night.

Contemporaneously with the appearance of the convulsions, a remarkable change was noted in the psychic state, and especially in the girl's character. She grew restless, quick-tempered and often revengeful. She had insomnia and anorexia and suffered from intense cephalalgia; therefore she soon exhibited a great and progressive deterioration. The bromide and tonic treatment that was regularly kept up for more than two years was ineffectual, both as to her general health and as to the number of the epileptic crises.

The girl entered this institution in May, 1900. She was very thin and dejected; she weighed 24.300 kilograms. The pupils reacted normally and the tendon reflexes were exaggerated.

On the first of July, 1900, the bromide treatment was entirely interrupted and the little patient underwent the treatment by injection, the blood-serum being obtained from a confirmed adult epileptic. The injections were made gradually, the first dose being 3 cubic centimeters. From the first the girl tolerated the injections well. At the end of the month, by increasing rapidly the dose, we had injected 65 cubic centimeters of serum.

At first the patient suffered from slight depression associated with some loss of weight, but afterward, especially in the second half of the month, she got remarkably better, both as to nutrition and as to the epileptic symptoms. The progress of the case was soon evident. The convulsions grew less intense and less numerous, so that on the 21st of the month they appeared for the last time. Meanwhile the insomnia, cephalalgia, fatigue and general depression from which the girl had suffered so long disappeared by degrees. Her appetite increased rapidly and at the end of the month she had gained 3 kilograms. Her facial expression was better and she became very good-tempered.

August: In this month 36 cubic centimeters of serum are injected in three doses. No phenomenon of any kind appears and the girl improves wonderfully. She is intelligent and good, and applies herself during the day in reading and embroidering. She often writes letters full of love to her parents, informing them of her progressive improvement. The weight increases to 31.500 kilograms.

September: The serum injections are definitely abandoned. Nevertheless the girl continues to improve and presents no longer any symptom of her former disease. The color of her skin has become rosy and she is well mannered and kind. The weight has now risen to 34 kilograms, that is, an increase of about 10 kilograms, in a period of three months.

In the month of October, her parents insisting upon it, the girl returned to her family. Her weight at the time of her release was 34.400 kilograms.

	Diary of the Convulsions	Weight in Kilograms.
May, 1900.....	124	24.300
June, 1900.....	132	24.300
July, 1900.....	16	27.800
August, 1900.....	—	31.500
September, 1900.....	—	34.000
October, 1900.....	—	34.400

At home the girl remained in the best physical condition and without any epileptic phenomenon for more than two months, that is, until January, 1901. Then, according to information obtained from the doctor of her family, she was taken with chronic bronchial catarrh, which caused emaciation and anemia. A few convulsions appeared after this, but they ceased in the following month, after gradual recovery from the bronchitis.

[To be continued.]

ONE WAY TO FIGHT CONTAGION.

BY CHARLES V. CHAPIN, M.D.,
OF PROVIDENCE, R. I.

An editorial in the Medical News not long since referred to the discouraging experience of a city which, after adopting new and stringent measures for combating communicable diseases, found that the diseases the control of which was attempted had increased rather than diminished. I suspect that this experience is not unique. We used to hear a great deal of hopeful prophecy about stamping out scarlet fever and diphtheria, but we still have them with us, though it is true they are not so common as in former years.

A study of the statistics of communicable disease in our cities indicates only a moderate success for our present methods of notification, isolation and disinfection. The history of Boston, for instance, is a discouraging one. Boston has more ample hospital facilities for caring for scarlet fever and diphtheria cases than any other large city. Its physicians are not surpassed by any as regards intelligence, education and public spirit. The proportion of cases reported is very large. Regulations in regard to isolation are stringent and unusually well enforced, yet the number of cases of scarlet fever and diphtheria is not perceptibly less than in other cities. In England, where many more than half the cases of scarlet fever and diphtheria in the large cities are removed to hospitals, these diseases prevail almost as extensively as in the United States. It is doubtless true that the increasing practice of isolation in these diseases has had its influence in their diminution, but the progress made has not been nearly so great as was hoped.

The writer has little doubt as to what is the chief reason for this. It is the existence in the community of a considerable number of infected persons who are only very slightly sick, or are not sick at all. A careful study of the cases of these diseases as they occur demonstrates that it is rarely possible to connect them with existing cases already recognized. Our methods of isolation, so far as they are applied to acknowledged cases, seem to be effectual. Every health officer is forced to admit that it is the unknown sources of infection which cause the trouble. The milder the infection, the less likely are the infected persons to be known, and the more difficult it is to control them. The present outbreak of smallpox is due to the mildness of the affection, very many cases being unrecognized. That many persons who are only slightly ill, or perhaps entirely well, are dangerously infected with diphtheria is well known. Bacteriological studies reveal the fact that from two to three per cent. of healthy persons are infected with growing diphtheria bacilli. It is true that the bacilli are not virulent in every case, but even if they are virulent in only a small proportion, we yet have enough to render it likely that these infected well persons are the chief factor in the spread of the disease.

While we are searching for better methods of dealing with these diseases, there is one line of warfare against them which ought to be pursued more energetically. If unrecognized infection is moving about among us, each of us must learn to protect himself. In diphtheria, tuberculosis, and scarlet fever in its early stages, and doubtless in smallpox, the virus is contained in the secretions of the nose and mouth. People should be taught to take care of their own secretions and to avoid contact with the secretions of others. In other words, they should be taught to be clean.

This matter was recently brought up in the Massachusetts Association of Boards of Health by Dr. Theobald Smith, and a committee of which he is a member drew up a report urging the teaching of cleanliness among school children and suggesting methods therefor. The means urged were as follows: (1) Lectures to teachers on the relation of cleanliness to health; (2) the distribution of circulars on this subject; (3) object teaching by the school department. The municipality should set an example in cleanliness in the provisions made for the pupils. The drinking cup used in common by the pupils should be abolished. The greatest care should be taken of the text-books, especially if furnished by the State, and soiled books should never be given out. Pencils, pens, etc., should be absolutely separate for each pupil. If slates are used each child should be required to use for erasing a cloth or sponge kept in its desk. If modeling clay is used each pupil's portion should be kept by itself. In general, it may be said that the school authorities should provide that each pupil shall have its own private school material, and that as little as possible shall be used in common.

In accordance with this plan, the following circular has recently been distributed among the teachers in the public schools in Providence, and similar but briefer rules will be distributed among the children. This circular is here given because it is believed to set forth some of the principles of cleanliness which should be practised and the reasons therefor.

Health Department.

Suggestions for the Teaching of Cleanliness Among School Children.

The poisons of some of the common and also of some of the most loathsome diseases are frequently contained in the mouth. In such cases anything which is moistened by the saliva of the infected person may, if it touches the lips of another, convey disease. The more direct the contact the greater the danger.

It is the purpose of health officials to keep in isolation all persons having communicable disease during the time that they are infectious. But in many cases this is impossible. Little restraint is put on certain mild diseases, as measles, whooping-cough, chicken-pox and mumps, and even such diseases as diphtheria, scarlet fever and tuberculosis are frequently so mild as to be unnoticed and children affected with them mingle freely with others. It is probable that in such

cases one of the chief vehicles of contagion is the secretion of the mouth and nose. It is believed that much can be done to prevent contagion by teaching habits of cleanliness. But if such instruction is to be effectual it must be continuous. The teacher must notice and correct violations of those rules as habitually as the violations of the more formal school rules are corrected.

Even if the question of disease and contagion did not enter into the matter at all the subject ought to be given more attention by teachers. Our schools should not only teach reading, writing and arithmetic, but it is perhaps quite as important that they should inculcate cleanliness, decency, refinement and manners. Cleanliness should be taught for its own sake even if it had no relation whatever to health.

Teach the Children

Not to spit; it is rarely necessary. To spit on a slate, floor, or sidewalk, is an abomination.

Not to put the fingers into the mouth.

Not to pick the nose.

Not to wet the finger with saliva in turning the leaves of books.

Not to put pencils into the mouth or moisten them with the lips.

Not to put money into the mouth.

Not to put pins into the mouth.

Not to put anything into the mouth except food and drink.

Not to swap apple cores, candy, chewing gum, half-eaten food, whistles or bean blowers or anything that is habitually put in the mouth.

Teach the children to wash the hands and face often. See that they keep them clean. If a child is coming down with a communicable disease it is reasonable to believe that there is less chance of infecting persons and things if the hands and face are washed clean and not daubed with the secretions of the nose and mouth.

Teach the children to turn the face aside when coughing and sneezing, if they are facing another person.

Children should be taught that their bodies are their own private possessions, that personal cleanliness is a duty, that the mouth is for eating and speaking and should not be used as a pocket, and the lips should not take the place of fingers.

A NEW CYSTOSCOPE, FOR THE SIMULTANEOUS CATHETERIZATION OF BOTH URETERS, AND FOR DOUBLE-CURRENT IRRIGATION OF THE BLADDER.

BY FREDERIC BIERHOFF, M.D.,

OF NEW YORK;

ASSISTANT ATTENDING SURGEON, DEPARTMENT OF GENITO-URINARY DISEASES, UNIVERSITY AND BELLEVUE MEDICAL COLLEGE; CORRESPONDING MEMBER OF THE FRENCH ASSOCIATION OF GENITO-URINARY SURGEONS.

The knowledge of the value of a comparison of the divided urines, collected simultaneously from both kidneys, as a means of diagnosis, and for the purpose of determining the degree of functional power of either or both kidneys, is rapidly gaining ground among surgeons. I need only mention the work of Albarran, Casper, Kümmel, Pasteur, Kelly and Brown in this field, and refer to the recent monograph of Casper and Richter for a complete exposition of the desirability of determining the condition and function of the kidneys prior to operation thereon.

With the single catheterizing cystoscope, the insertion of the first ureter-catheter was a comparatively easy task; but the insertion of the second (the first remaining *in situ*) was exceedingly difficult—at times even impossible. Owing to the fact that in order to allow the catheter to remain in the ureter, it was necessary, in withdrawing the cystoscope, to turn the entire instrument (and with it the catheter) so that the beak pointed upward, it frequently happened that the catheter became turned about the lamp and, owing to the occasionally present cramp-like contraction of the compressor urethræ muscle, pressed tightly against the instrument, and, by the withdrawal of the latter, also drawn out of the ureter. If the operator succeeded in leaving the first catheter *à demeure*, it frequently occurred that, on the insertion of the cystoscope a second time, the first catheter was found to lie in the way, to obscure the field of vision and to make the insertion of the second catheter into the other ureter very difficult, or impossible. On withdrawing the cystoscope the second time, there was present the additional danger that, owing to the compression of the first catheter against the outside of the cystoscope, this catheter or both catheters would be drawn out of the ureters.

To obviate these difficulties has been, of late, the aim of several. Casper has devised an instrument for the catheterization of both ureters, and it is described and illustrated in the monograph published by himself and Richter. Tilden Brown and W. K. Otis have each devised instruments for the same purpose.

The instrument which I have devised, and which is here described and illustrated, is designed to permit (1) the examination of the entire bladder; (2) the renewal of the filling-fluid, without removing the instrument, should the fluid become turbid during the operation; (3) the catheterization of one or both ureters during the one sitting; (4) the facilitation of the procedure of leaving one or both catheters *à demeure*.

It is a modification of the improved Nitze-Albarran catheterizing cystoscope and consists of a cystoscope upon which is the *movable* catheterizing portion (see Fig. 1). The latter contains two separate tubes in which the catheters pass, which terminate, at the outer end, in two separate cannulæ capped by the usual screw caps. At the inner end they terminate in two small, movable knee-mechanisms, which are controlled and moved by the large screw, as in the single catheterizing instrument. The size of the instrument is the same as that of the single catheterizing cystoscope (average 23 Charrière; 18 in the short, 28 in the long axis). The catheters to be used are somewhat smaller than those used for the old

instrument. I prefer to use one black and one brown catheter, in order to avoid all chance of mistake in the collection of the urines. There are also two stop-cocks to replace the screw-caps upon the cannulæ, when double-current irrigation is to be employed. The catheterizing portion, being removable, can be sterilized by boiling. The cystoscope itself must be sterilized by immersion in an antiseptic solution.

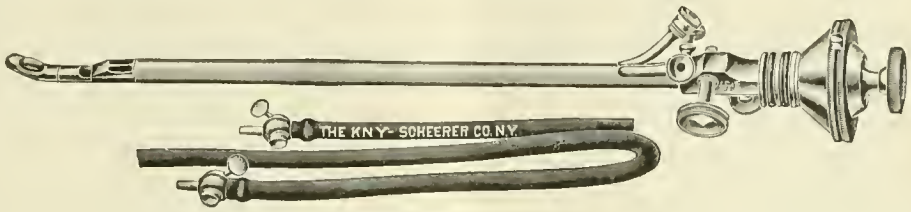

Fig. 1.

The method of using is as follows: The black catheter is inserted into the cannula upon the operator's left hand, the brown into the right. The instrument is then inserted as is the old instrument, and one or other ureter sought for and catheterized, the catheter being inserted about 4 to 5 cm. into the ureter. The knees are now turned down again, and the other ureter is located. During this latter procedure the first catheter moves out of the field of vision, and may be entirely disregarded by the operator. The second ureter is now catheterized, the knees again turned down, and the instrument turned so that the operator may assure himself, before withdrawing it, that both catheters are *in situ* (see Fig. 2). The lamp is then extinguished and allowed to cool, and the cystoscope turned upward, within the catheterizing portion, so that the beak points toward the median line of the abdominal wall, the catheterizing portion meanwhile being held, and continuing to point downward (see Fig. 3). The instrument is then slowly withdrawn, its removal being compensated for by a gradual insertion of more of the catheters into the cannulæ. When the knees of the instrument, with the catheters, appear at the meatus, the catheters are fixed, at the urethral orifice, with one hand, and the cystoscope steadily withdrawn with the other. It will be seen that, during the process, the black catheter has come to lie on the patient's left side, and the brown on the right. It is thus an easy matter to distiguish and collect the separated urines. It will be found, on following the above directions, that the entire procedure is much easier to carry out than with the old instrument. It has been used by me, since its completion, in three instances, two in the male and one in the female, and with *complete satisfaction.*

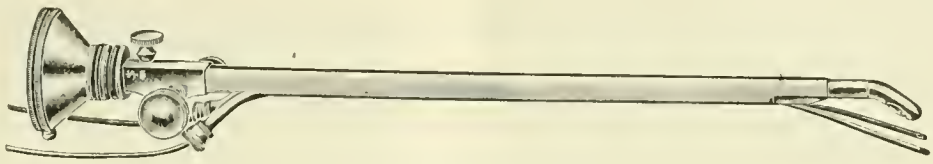

Fig. 2.

Should the fluid become turbid, during the course of the examination, the catheters and screw-caps may be removed and the stop-cocks, attached to rubber tubes, inserted into the cannulæ. The streams then, flowing through separate tubes, are kept distinct, and the one tube may be used for the inflow, the other for the outflow. It is, of course, not intended that clots or large shreds be removed, but simply the filling-fluid removed. In refilling, after irrigation, one stop-cock is closed, and the bladder filled through the other tube. Should it be desired to use the instrument as a single catheterizing cystoscope, one tube may easily be closed with the stop-cock.

Fig. 3.

The instrument was made for me by the Kny-Scheerer Company of New York, and represents in its entirety a product of American workmanship. It is a pleasant duty, in closing, for me to thank Mr. R. Kny, of the above firm, for his great kindness in placing their resources at my command, and to their assistant, Mr. Farner, for the masterly way in which all my suggestions were carried out.

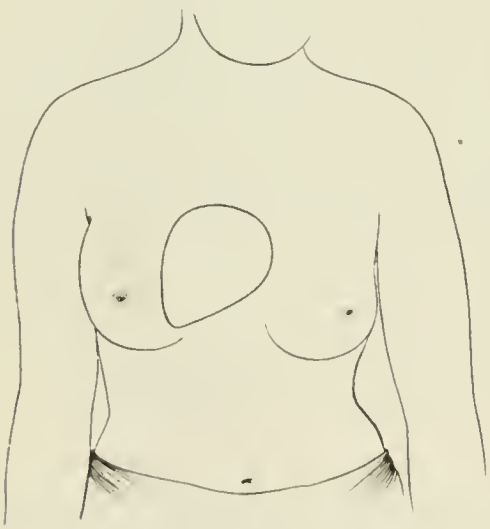
717 Madison Avenue.

CONGENITAL DEXTROCARDIA.

WM. EDGAR DARNALL, A.B., M.D.,
OF ATLANTIC CITY, N. J.;
PHYSICIAN TO THE ATLANTIC CITY HOSPITAL; THE MERCER HOUSE FOR INVALID WOMEN; FELLOW OF THE AMERICAN ACADEMY OF MEDICINE.

Cases of transposed viscera are always interesting, because they are rare and because they are deviations from the normal. Dextrocardia has been observed before, but it is rare enough for each new case to afford some points of interest and to justify its being recorded.

Mrs. F., aged sixty-nine years, widow of a clergyman, was referred to me from West Virginia. She consulted me for pains which she described as radiating down her arms. She also complained of digestive disturbances with the formation of gas in the stomach. She told me she had always contended that her heart was on her right side, but her doctor had laughed at the idea. There was, she said, such a "surging" on that side whenever her attacks of palpitation came on. I asked for an examination more out of curiosity than for any other reason. The examination revealed the following condition: The apex beat was an inch and a half below and half an inch within the *right* nipple. The superficial area of dulness extended from the apex, at a point between the fifth and sixth costal cartilages, to the median line of the sternum on the *right side;* thence up to the level of the upper border of the fourth costal cartilage, and from this point back to the apex. The diagram shows the position occupied by the heart. The sounds were normal at



Congenital dextrocardia.

the apex and pulmonary interspaces, and the condition had never been the source of any discomfort to her except at times a disagreeable palpitation, and in her younger days a tendency to syncope, which was easily induced by any sudden emotion or exertion. She had all her life been a remarkably healthy woman until within a few years. She had a small tumor removed from her left breast, at the age of eighteen, which was due to a traumatism. About six years ago the right breast was operated on for a small mass which was undoubtedly carcinomatous. She is now somewhat cachectic and the telltale pains in the arms led me to look further for secondary trouble. A small indurated area could be felt at the pyloric end of the stomach, which, together with the history and the digestive disturbances, made the diagnosis of malignant disease clear.

This trouble however has no bearing on the position of the heart, which has existed since birth, and is mentioned simply to emphasize the significance of the aching pains in the arms as betokening secondary involvement with malignant disease. No displacement of any other viscera could be detected, and the case is of interest only as an anomaly.

SOMNOLENCE AND LOSS OF MEMORY RESULTING FROM CHOLESTEATOMA OF THE MIDDLE EAR.[1]

BY FRANCIS R. PACKARD, M.D.,
OF PHILADELPHIA;
PROFESSOR OF DISEASES OF THE EAR IN THE PHILADELPHIA POLYCLINIC; AURIST TO THE OUT-PATIENT DEPARTMENT OF THE PENNSYLVANIA HOSPITAL.

The Proceedings of the Philadelphia County Medical Society for December, 1901, contain the report of a case of "Somnolence Caused by an Ear Lesion" by Dr. W. G. B. Harland. The patient was a boy thirteen years of age, whose personal history somewhat reminded us of that recorded of Dickens' fat boy in "Pickwick Papers," in that he would fall asleep when sent to a store and waiting for his order to be filled, or when at table, and indeed on every other possible occasion. Otherwise the boy was healthy and his condition was accounted for by the presence of a chronic suppurative otitis media, the pus of which had been dammed up by a mass of cerumen in the external auditory canal. After free exit had been given to the discharge, the boy's symptoms cleared up.

The case recalled to my mind one of a somewhat similar nature which came under my care last summer.

H. B., aged twenty-three years, a master mechanic, was referred to my office by Dr. J. E. Talley on July 9, 1901. For upward of twelve years he had had at intervals a discharge of foul-smelling pus from the left ear. This symptom, however, seems to have given him but little concern, as he had never considered it necessary to undergo any course of treatment for its relief. During the last year the patient had noticed that his memory was failing and that he was subject to attacks of intense sleepiness alternating with occasional headaches. This forgetfulness was such that he could not remember the simplest things; he would forget the names of people, and

[1] Read before the Section on Otology and Laryngology of the College of Physicians of Philadelphia, Jan. 15, 1902.

the things which he had intended to do in his work, and was absolutely unable by any effort to concentrate his memory so as to remedy the defect. Examination, after cleansing out a quantity of inspissated pus from the external auditory canal, revealed almost total destruction of the drum with a mass of granulation tissue covering over the upper part of the exposed middle-ear cavity. It was impossible to detect dead bone with the probe. There was marked bulging of the upper posterior wall of the external auditory canal. Operation was advised, and on July 13th, assisted by Dr. Walter Roberts, I opened the mastoid and proceeded to remove a great quantity of dead bone in immediate proximity to the middle-ear cavity with huge cholesteatomatous masses in the interior of the mastoid process. The patient made an uninterrupted recovery, and when last seen in December, 1901, five months after the operation, told me that he had had absolutely no return of headache or of somnolence, and that his relatives noticed that he was able to remember things and was much brighter mentally. There was no discharge from the ear.

In this case I had expected to find some evidence of meningeal trouble upon opening the skull, but, although a considerable surface of brain membrane was exposed, there was no evidence whatever of any pathological condition.

In the discussion of Dr. Harland's paper Dr. Burnett remarked "that somnolence from otitic influences is rare and its etiology obscure." He stated that the case of Dr. Harland was the only one which had come under his personal observation. Dr. Burnett divides these somnolent and syncopoid states depending upon aural lesions into two classes, those in which there is extension of the suppuration of the purulent ear disease to the cerebral surface, and those in which the brain symptoms are due to direct inward pressure of the stapes.

I do not doubt that in the case which I have reported the cerebral symptoms were the result of at least a congestion of the meninges and possibly of a slight recurrent meningitis. In view of Dr. Burnett's statement as to the rarity of the condition it seems to me that the case is worthy of record.

URTICARIA OF THE UPPER RESPIRATORY TRACT.[1]

BY LEWIS S. SOMERS, M.D.,
OF PHILADELPHIA.

The erratic and migratory character of the lesions of urticaria upon the dermal surface and their extensive distribution would naturally lead one to expect the presence of the eruption upon the mucous membrane of the upper air tract with greater frequency, and, although a careful search of the literature reveals less than two score cases, yet the affection undoubtedly involves the mucosa much more frequently than the reports of such cases would indicate. One of the earliest recorded instances of the disease involving the throat was in 1862, in a male who had taken a large dose of quinine for malaria and immediately developed severe itching of the neck, chest, arms and legs, accompanied by the typical wheals of urticaria, continuing until the following day, when a sudden attack of suffocation with laryngeal stridor and aphonia developed, but all the symptoms rapidly subsided under treatment.

That the mucosa is not involved more frequently is difficult to explain, although, as suggested by Packard, its relative infrequency is probably best explained by the absence of irritation of the mucosa such as is produced on the dermal surface by the clothing and unwarmed air. This is hardly plausible even as a negative explanation, however, and some more subtle factor must exert its prophylactic action in the large number that suffer from dermal urticaria and in whom the respiratory tract presents no abnormal changes.

Corresponding to the affection as seen upon the cutaneous covering, it may be either acute, when the symptoms usually assume a most alarming aspect, or chronic, as is more rarely the case. In either variety, but especially in the former, two types of the disease may be clearly distinguished, the first being that in which the skin eruption makes its appearance primarily and is followed by the development of the wheals upon the mucous membrane, while in the second type, the difficulty of diagnosis is greatly enhanced by the appearance of the respiratory symptoms first, followed later by the skin eruption. In this latter form the disease closely simulates other laryngeal affections accompanied by edema and respiratory distress, and in the absence or delayed appearance of the cutaneous wheals the diagnosis may be impossible, the disease not being recognized at all, or, as has been suggested by others, the affection is considered to be asthma.

Milton has reported two cases, the first showing the usual clinical variety with the initial skin lesion and later involvement of the mouth and throat, while his second patient belonged to the latter class, beginning with great difficulty in breathing, which subsided upon the development of wheals on the skin. Merx illustrates the chronic form of the disease in a neurasthenic male of thirty-four years, with repeated attacks of dysphagia and burning in the larynx and pharynx which disappeared in a few hours after treatment. The wheals came on in a series of irregular attacks and during its course the uvula, soft palate, tongue, epiglottis and vocal cords were involved. Gaudier records an interesting case in which there was sudden onset of itching and dryness of the mouth with a foreign body sensation in the throat. The mucous membrane of the oropharynx and epiglottis was swollen from the wheals, but no dermal lesions appeared during the attack, the diagnosis being made by the sudden appearance of the affection after partaking

[1] Read before the Northwestern Medical Society of Philadelphia, Nov. 5, 1901.

of food, the physical appearance of the lesions, and its complete disappearance in twenty-four hours.

The acute febrile form of urticaria is but rarely seen. It appears suddenly, the eruption is scarlet in color, with great swelling; and, while the face, trunk and limbs are usually the seat of the eruption, it may involve the larynx and pharynx with the production of dangerous obstructive symptoms.

The following case was one in which urticaria appeared simultaneously on the dermal and mucous surfaces and bore a definite relation to the ingestion of improper food.

Miss L. A., eighteen years of age, of robust health and without any history of illness except hay-fever which had existed from August to October for three years. The attacks of hay-fever were typical even to the hour and day of their appearance, and she had suffered from the constant watery nasal discharge, irritated conjunctivæ, sneezing, palate and chin pruritus until the first frost, when the symptoms would subside and no demonstrable lesions of the upper respiratory tract would be evident. On several occasions she had slight attacks of urticaria limited to the trunk and arms, and she was able in every attack to trace the exciting cause to the partaking of almonds of which she was extremely fond. Other food such as strawberries, shellfish and even nuts of various sorts, with the exception of almonds, could be partaken of with impunity; for a number of years she had given up eating almonds on this account.

While under treatment during her third attack of hay-fever, I was hurriedly summoned as it was supposed she was having an attack of fatal suffocation. On my arrival there was great dyspnea, inspiratory efforts were short and feeble, the face was cyanosed, there was suprasternal retraction, and the mouth was widely open in the patient's violent efforts to obtain sufficient air. Her features were unrecognizable from the presence of multiple wheals, and, between gasps in a voice which was almost aphonic, she complained of great physical prostration and of burning and itching from the urticarial eruption which covered the entire surface of her body. The tongue was swollen so that it was protruded with great difficulty, the uvula was lobulated, due to the presence of two giant wheals, and almost filled the arches, while the mucous membrane of the mouth, pharynx, epiglottis and the aryepiglottic folds as far as could be seen were swollen from the eruption.

The oropharynx was sprayed with a solution of cocaine and, as the swelling subsided, the larynx was seen to be involved to such an extent that but a minute fissure existed below the false cords, which were almost approximated; below this point, however, no eruption was apparently present. She was given small pieces of ice in the mouth, a dilute carbolic wash was used on the dermal surface and the bowels were freely moved by high injections, later followed by a large dose of salts. The cocaine and ice rapidly reduced the swelling of the respiratory tract, within an hour the mucous membrane had resumed its usual aspect, and all the symptoms referred to this particular region had disappeared, with the exception of nasal stenosis, which had not been considered to any extent previously. On examination of the nasal chambers the mucosa was seen to be covered with wheals, but as they were subsiding no direct treatment was applied. The skin changes were about five hours in disappearing; on the following day she was perfectly well. An interesting phenomenon noticed during the height of the attack was the presence of apparently complete deafness, due to the mucous membrane of the tympanic cavity and Eustachian tubes being occluded by the wheals. The cause of the attack was readily explained, as she had given way to her appetite for almonds and within a few minutes after partaking of a considerable number the threatening symptoms developed.

The predisposing cause as regards the liability to attack of the upper respiratory tract is apparently unknown; in my case no structural abnormalities existed; while this is apparently true in the majority of reported cases there are a few in which slight deviations from the normal were observed, but the evidence is against this playing any part in the tendency to the eruption here. A general idiosyncrasy of the patient, a peculiar vasomotor weakness of the mucosa and the effect of an exciting cause, such as the eating of improper food in the individual case, must be taken into consideration. The association of urticaria of the mucosa with hay-fever is rarely observed, although its presence upon the dermal surface is not at all uncommon and the disturbed vasomotor equilibrium at such times strongly predisposes the hay-fever sufferer to attacks of the ordinary forms of urticaria in the presence of an active exciting cause.

In a person predisposed to urticaria the development of the wheal upon the mucous membrane of the nose, pharynx or larynx may result from any of the usual exciting causes, such as irregularities in diet, certain foods and drugs and contact with animal or plant life, these factors, of course, operating upon the dermal surface in the majority of instances, while the mucous membrane involvement may be considered as a complicating incident, except in those cases in which the membrane is at first affected as the result of the ingestion of certain foods or drugs, or due to an idiosyncrasy of the individual as yet undetermined.

In severe cases the general symptoms antedating the appearance of the wheals upon the mucosa are often distressing, as in a case reported by Woodbury, in which there were rapid pulse, profuse perspiration on the forehead and fainting, while in Chittenden's patient there were attacks of recurrent hematemesis. Before the eruption appears a vague feeling of distress may be bitterly complained of and great physical weakness and nausea may also be experienced, while in cases of

a mild type little or no complaint may be made until difficult breathing is first noticed.

Except for the nervous element dependent upon the skin lesions, the majority of the general symptoms, such as the change in pulse-rate and the feeling of impending evil, are the result of the beginning impairment of respiration, this usually being the first symptom noted, while if the posterior pharyngeal wall or esophagus be involved dysphagia becomes marked. The suffocation increases with the increase in size and number of the wheals, the face becomes cyanosed, the voice is hoarse or to a great extent lost, depending principally upon the laryngeal involvement, although it may be considerably altered from the swelling of the uvula and epiglottis.

A sense of burning and pruritus may be referred to the affected mucous membrane, or one may preponderate for a time with sudden alternations in the character of the subjective phenomena. This is especially noted in mild cases, as in those in which the respiratory distress is great little attention will be paid to minor symptoms, so that the degree of paresthesia of the mucosa bears little or no relation to the extent of the swelling. In the chronic form this pruritus may be quite prominent and resemble the sensation produced by a foreign body, as in the case of chronic urticaria of the mucosa seen by Freudenthal. When the epiglottis or larynx becomes involved, the dyspneic symptoms rapidly assume a most alarming aspect and a condition in all essentials similar to edema of the glottis results, with the suffocative attack increasing in intensity as the air space becomes more and more encroached upon. The wheals here and higher up in the air passages are invariably accompanied with some increase of the local temperature, but this, like the pruritus, is fugacious in character and rapidly disappears as the lesions subside.

In the acute cases, the mucous membrane of the oropharyngeal cavity, nose and larynx may be involved in part or as a whole with the typical swellings of the disease, differing in no respect from those seen on the skin, but appearing as tense, shining elevations, of varying shades of red, with a lighter hue at the summit of the elevation, while in some cases the apex of the wheal is a shining yellowish-white from local restriction of the circulation. But a limited area may alone be involved, as in the case seen by Hinsdale in which the brunt of the swelling was borne by the uvula, which was enlarged, edematous and allowed with difficulty the entrance of air to the larynx; or the tongue may be affected, as in cases reported by Hutchinson and Hamilton, the swelling being so great in the latter's case that incision had to be resorted to. The wheals are usually round or ovoid in appearance but they may coalesce in the limited space of the air tract and form erythematous swellings of considerable areas of the mucosa. Again they may appear as irregular patches, and the size and form will vary greatly as successive crops develop.

In the chronic form, as in the case recorded by Goodale and Hewes of a man with urticaria of the tongue, the symptoms are not so violent as in the acute variety, although the mucous area may feel sore and urticarial patches may be present to a greater or less degree for months or even years.

The development of wheals upon the mucosa, preceding any dermal manifestations may, especially if intralaryngeal in origin, lead to serious errors in diagnosis; and it is not at all improbable that cases of mild urticaria of the mucous membrane of this region are not diagnosed as such, but are treated on essentially different lines from those which would be adopted if the nature of the affection had been recognized.

The duration of the eruption upon the mucosa, like that upon the skin, is commonly but a few hours in the acute cases, although some of the symptoms may last for several days, and evidences of the wheals, especially upon the lingual surface, may be seen for nearly a week after all respiratory distress has disappeared. In the cases in which the eruption appears first on the mucosa, it may be an hour or more before the dermal signs become prominent, but as they appear the primary lesions recede, as a rule, and under appropriate treatment it becomes only a question of a few hours before the alarming aspects have entirely subsided. Remissions may however take place, but they are chiefly confined to the dermal wheals and not to the mucosa, although the pruritus attendant upon the eruption on the mucosa may from time to time become augmented, with slight increase in the number of the wheals. When the urticaria appears upon the dermal surfaces primarily, the mucosa is usually not involved until a number of hours have elapsed from the full development of the dermal wheals, and when developed is apt to remain somewhat longer than when it occurs primarily in the larynx or pharynx. The subsequent course, however, does not differ in any essential respects from the primary mucous membrane cases. Thus, in Gibb's patient on the evening of the second day the eruption diminished, but hoarseness and dysphagia came on with increased intensity, while on the following day the patient was well. Fortunately, the predilection of the disease is toward the skin, and in practically all the acute cases the wheals appear upon this part more or less rapidly, to the great relief of the local lesions.

No difficulty should be experienced in recognizing urticaria of the upper respiratory tract when the lesions are also present upon the cutaneous surface, and it is only the cases in which the eruption is limited to the mucosa that will present any difficulty. The local appearance of the wheals differing from other forms of eruption seen upon the mucosa, the apparently inflamed condition of the parts, with separate areas of local ischemia situated at the summit of the reddened patches, and the migratory property of the wheals, with their fugacious character, will all aid in the recognition of the individual case. Occasionally it will take the form of acute edema of the mucosa, or it may be practically limited to the epi-

glottis, when its recognition will become almost impossible, but in all cases the symptoms are more or less distinctive, as they occur suddenly, are evanescent and produce pruritus akin to that of the dermal lesions.

The history of previous attacks of urticaria, even if they have not involved the mucosa, is an important aid in diagnosis and in practically all cases before the disturbance of the mucosa has entirely subsided, the appearance of isolated or multiple wheals on the skin will clearly indicate the nature of the affection. The presence of an unrecognizable cough, or periods of minor obstruction to breathing associated with irregular attacks of cutaneous urticaria, should at least lead to the suspicion of some relation existing between the two phenomena, and the placing of the patient under an appropriate treatment based upon such an association may be the means of elucidating some of these obscure cases which are usually unrecognized.

MEDICAL PROGRESS.

PATHOLOGY AND BACTERIOLOGY.

Relation of Angiomata to Carcinoma.—Stimulated by the recent article of Leser on the frequent coexistence of multiple skin angiomata and carcinoma and the help in diagnosis which the former offer, D. Gebele (Münch. med. Woch., Jan. 28, 1902) examined 21 cases of undoubted carcinoma and 200 of a number of other diseases. Of the former, only a little over half presented the angiomata; in the latter they occurred in 43 per cent. According to these observations, they lack all value for purposes of diagnosis and simply show a retrogressive change in the tissues, which naturally is most marked in advanced age, when malignant tumors also are more prevalent.

Differential Staining of Blood Films and Malarial Parasites.—Among the new blood stains which are rapidly being devised that recommended by J. H. Wright (Jour. Med. Research, Jan., 1902) deserves especial mention. The author claims that it not only gives a differential staining for the chromatin and cytoplasm of malarial parasites, but as a general staining method for blood is superior to Jenner's in that it sharply differentiates the neuclei and cytoplasm of the lymphocytes and large mononuclear leucocytes as well as the granulations of the leucocytes in general. For the preparation of the staining fluid one per cent. of methylene blue (Grübler) is added to a one-half-per-cent. aqueous solution of sodium bicarbonate in which the bicarbonate is thoroughly dissolved. This mixture is then steamed in an Arnold steam sterilizer for one hour, counting from the time after "steam is up." When cold the mixture is poured into a large dish or flask and a sufficient quantity of a 1-1000 aqueous solution of eosin added until the blue color is lost and a purple color appears with a scum of a yellowish metallic luster on the surface. During the addition of the eosin the mixture should be constantly stirred or shaken. When the addition of the eosin is complete a finely-granular black precipitate appears in suspension in the mixture. This is removed by filtration without washing and when thoroughly dry is added to pure methylic alcohol to saturation. This saturated solution is filtered and to the filtrate is added 25 per cent. of methylic alcohol. This dilute alcoholic solution is the staining fluid. The technic for using the stain is as follows: (1) Make films of the blood, spread thinly and allow them to dry in the air. (2) Cover this preparation with the staining fluid for one minute. (3) Add water, drop by drop, until the mixture becomes semitranslucent and a yellowish scum forms on the surface. Allow this mixture to remain on the preparation for two or three minutes. (4) Wash in water until the film has a yellowish or pinkish tint in its thinner or better spread portions. (5) Dry between filter paper and mount in balsam.

Branching in Bacteria with Special Reference to B. Diphtheriæ.—In recent years much attention has been given by investigators to the branching forms of various bacilli so frequently observed. The subject is of great importance from the viewpoint of the classification of such micro-organisms. As the result of detailed study H. W. Hill (Jour. Med. Research, Jan., 1902) shows that passive degenerative changes in dead or dying bacilli may give rise to slight irregular projections which distinctly simulate branches. As a part of the active development of the diphtheria bacillus, active branching by apparent budding, ending in the production of an oval or elliptical body, probably capable itself of further development and the production of new rods, may occur in very young cultures, the parent stem then degenerating. As a part of the active development of the diphtheria bacillus, branching similar to that described, but terminating in an ordinary diphtheria rod-like body and without any degeneration of the parent stem at the point of origin, may occur within twenty-four hours of inoculation; and this new rod may segment in the ordinary way or itself produce branches, terminating in rods similar to itself or in oval bodies such as described. Various modifications of all the processes of branching probably exist. The origin of the active multiplicative branching may be reversionary or evolutionary or merely due to special conditions of growth not understood at present. According to the latter view, the active forces usually resulting in fission may at times undergo a lessening of tension or some other modification which results in a change

in direction of their activities. Whether such a change is retrogressive or progressive has not as yet been determined.

Dermoid Cysts and Teratomata of the Anterior Mediastinum.—The general subject of dermoid cysts and teratomata is one of much interest. While they are comparatively common in certain locations, as the ovary, their great infrequency in the anterior mediastinum has led H. A. Christian (Jour. Med. Research, Jan., 1902) to report a case which recently came under his observation. The patient, a female thirty-eight years of age, had complained of indefinite pulmonary symptoms for six years. For two years previous she had coughed up hairs at intervals. During the last few weeks there had been several attacks of hemoptysis. On physical examination there was dulness in the right chest which diminished in extent after attacks of coughing during which much material was brought up. A few hours before death there was a gush of blood and pus from the mouth and with this material a few hairs were mixed. At autopsy a tumor as large as a cocoanut presented itself in the lower portion of the anterior mediastinum. It extended from the diaphragm nearly to the bifurcation of the trachea and was attached to the inner surface of the right lung from its base to a point 6.5 cm. below its apex. When opened the tumor presented a cavity containing about 200 c.c of whitish-yellow, semi-solid material, full of long, delicate, curly, blond hairs. Over the anterior part of the wall of the tumor and pleura there was in places a layer of fat and fibrous tissue 5 to 6 mm. thick. In the right half of the tumor there were small, scattered, bony plates adherent to the wall. The entire inner surface of the tumor was trabeculated. Microscopical examination showed the characteristic appearance of teratomatous growths. After reviewing the literature of the hitherto reported cases the author concludes that teratomata in the anterior mediastinum generally give evidence of their presence during early adult life and are of relatively long duration. Their most frequent position is immediately behind the upper portion of the sternum. They may be classified as follows: (1) Tumors of ectodermal origin with the addition of some tissue from the mesoderm—dermoid cysts. (2) Tumors derived from all three germ layers—teratomata. (3) Dermoid cysts or teratomata which in some part of their structure show evident malignancy. The coughing up of hair is pathognomonic of this mediastinal condition. Cure is possible only through surgical procedure. The genesis of these tumors is to be referred to the fetal period of life.

SURGERY.

Quinine in the Treatment of Wounds.—It may seem unnecessary to offer a new means for treating wounds, but in this capacity quinine has lately come to the front. J. Hevesi (C'blatt. f. Chir., 1902, No. 1) has been working along these lines lately, and offers a new form of quinine which is called lygosinate, which has been prepared synthetically from salicylaldehyde by Prof. Fabinyi. One of the same group of salts, namely, the lygosinate of soda was presented in 1898 to the International Congress for Hygiene at Madrid, by Prof. Marschalko, who claimed great efficiency for it in soft chancre and in gonorrhea in women. For surgical purposes the drug recommended itself on account of its insolubility, and less so for its rather strong decolorizing influence. Later Fabinyi produced a scarcely soluble preparation, using quinine and thus producing diorthokumarketon. The finely-divided orange-colored powder is scarcely soluble in water, but readily so in alcohol, benzine, and chloroform. It contains 70.8 per cent. quinine. In boiling oil it passes into solution, five parts in one hundred. It has a bitter taste, and an almost imperceptible, slightly aromatic odor. In the hands of this author the bacteriological experiments proved that the drug has a very remarkable power to destroy micro-organisms. No cases of poisoning from the drug among animals were seen. The drug was used as a powder for dusting on wound-surfaces, for impregnating gauze, and other dressings, for suspension in glycerin, and finally for combination with the gum on adhesive plaster. A thin layer of the powder dusted on was used in many cases of unclean wounds in patients who were walking about, in foul, gangrenous conditions, and the like. In all these it acted as a deodorant and an antiseptic, so that the poisonous secretion soon became harmless, odorless and only slightly purulent. Meanwhile the whole wound became a lively, healthy area of granulations. Ulcerating cancer also was deodorized and dried by means of the powder. In cases of bone disease a ten-per-cent. suspension of the drug in glycerin was injected into the wounds or the powder itself was rubbed in. Here also similarly successful results were obtained. Sinuses and fistulæ yielded to it. Similar other well-known chronic surgical conditions are benefited. Bleeding, especially oozing from the parenchyma of organs, is easily checked with the aid of this preparation. Most important of all is the fact that it is not poisonous because so little of it is absorbed.

Nephrectomy.—In the diagnosis of various kidney lesions necessitating excision of the organ, several important methods of examination and investigation have been instituted. L. J. Ladinski (Med. Rec., Feb. 8, 1902) in presenting cases of calculus and pyonephrosis, tuberculosis, new growth and suppuration, points out some of the valuable methods employed in diagnosis. Catheterization of the ureters gives much information of a definite character at times, but it is very difficult in the male and there is danger of carrying infection up the ureter. The cystoscopes of Nitze and Kelly and the segregator of Harris assist much in determining the character of the urine from the two ureters. The X-ray may be used with success in renal calculus, but is not always reliable. The freezing-point test of the urine (cryoscopy) is a test of the function rather than of the structure of the organ, and when a part of the kidney has been destroyed or removed it lends no information concerning the condition of the remainder. A thorough examination of the urine is, however, necessary in order to arrive at a satisfactory diagnosis of the nature of the malady. In calculus the urine is invariably acid, there are microscopical or macroscopical traces of blood and an excess of crystals of the salts composing the calculus. If there is an accompanying pyonephrosis the urine is the same in character as in suppuration. In tuberculosis there may be no change in the urine in the early stages; in the advanced cases varying amounts of pus and blood may be found. At first the urine is acid, but it may become alkaline afterward. The amount of urine is increased early, but the urea is much diminished. Tubercle bacilli are sometimes difficult to find. There are very few changes indicative of new growth. Small amounts of blood may be found in the urine and when the pelvis of the kidney is involved elements of the growth may appear. In suppuration, when the process is in the kidney substance, the urine is acid and purulent and frequently contains blood; when the pelvis is involved the urine is acid at first, but later it becomes neutral or alkaline, especially so if the mucosa of the

bladder become affected. The principal symptoms common to these kidney lesions are: (1) pain, (2) hematuria and pyuria, (3) tumor, (4) frequent and painful urination, (5) polyuria or anuria, (6) febrile condition. The differential points are as follows: In calculus, besides the renal colic, there is pain, due to the presence of the stone, which radiates into the pelvis, paroxysmal in character and increased on exercise. In tuberculosis the pain is usually slight. In new growth, it is generally severe, radiating in all directions. In suppuration it is variable. In calculus, there is very little hematuria, except during the passage of a stone, when there may be considerable. In the other diseases, blood is occasionally present. Frequent and painful urination is always present in tuberculosis (in fact, may be the first symptom) and occasionally appears in calculus and suppuration. Polyuria is especially noted in tuberculosis. Anuria is due to obstruction of the ureter. In calculous pyelonephritis there is a slight elevation of temperature, in tuberculosis a characteristic evening rise and in suppuration a continuous or intermittent high temperature.

Spinal Anesthesia with Tropacocaine.—Another addition to the already rich literature of spinal anesthesia is the article by K. SCHWARZ (Münch. med. Woch., Jan. 28, 1902), who has tried cocaine, eucain B. and tropacocaine extensively and expresses his preference for the latter, which he has used in over a hundred cases. His technic does not differ from that usually described. For operations on the rectum and lower down, 5 centigrams were injected; for higher regions, 6 centigrams were sufficient. In contrasting the effects and after-effects of tropacocaine injections with those of cocaine injections, the author finds (1) that during the operation nothing more than a slight pallor or cyanosis appears; vomiting is exceptional and occasionally there is some slowing of the pulse and involuntary discharge of urine and feces; (2) vomiting after the operation is also unusual; (3) headache, the most prominent symptom after cocaine, was present in but 11 per cent. of the cases, but was not nearly so severe in intensity; in a few it came on only during the third or fourth day and lasted two days; (4) rise of temperature with chills is always absent; the highest temperature recorded was 38.2° C. (100.7° F).

Effects of the X-ray.—The ordinary burn from the employment of the X-ray can at present be largely obviated by a better knowledge of the method. There is a certain condition, however, which differs from the so-called burns, and in which the skin of the exposed part becomes red, thickened, and as hard as in scleroderma, and is accompanied by excruciating boring pains. J. C. JOHNSTON (Phil. Med. Jour., Feb. 1, 1902) believes that this condition should be classed with the other precancerous keratoses, a preliminary stage of the squamous-celled type of epithelioma, in which the only change is a thickening of all the layers of the surface epithelium, or, in other words, in which cornification is the principal clinical feature. He reports two cases, one, the most marked, in a surgeon who employed the X-ray extensively. When first seen the skin of the hands was dry and scaly, the cuticle thin and atrophic, and on the dorsum were a number of hard, cornified growths, translucent and pearly. Examination of certain ones, after excision, showed marked malignancy with tendency to deeper invasion. The patient stopped his work and rest was enjoined. To prevent irritation of the skin a mixture of equal parts of hydrogen peroxide and glycerin gave the best results. After some months a recurrence was noted at the edge of the scar, which was excised down to the tendon and the wound grafted. This, however, showed no malignant traits, although the remaining cornifications are probably potentially malignant. Early and complete removal is therefore recommended.

Stammering Bladder and Urethra.—Sir James Paget was the first observer to call attention to and to name this interesting and relatively frequent condition. His clinical picture is extremely graphic. "The patient can often pass his urine without trouble, especially at customary times and places, and when he does so the stream is full and strong and he has nothing the matter with him. But he is in trouble if anyone is looking at him or if he is hurried, as at a railway station. He cannot pass a drop of urine, or, after a few drops there comes a painful check and the more he strains the less he passes; and then complete retention may ensue and overfilling of the bladder. Nearly all these cases find a parallel in the phenomena of stammering speech. In both alike there is usually a history of the difficulty having been felt in early life; in both alike are observed the strong influences of habit and association of ideas, the effect of transient changes in the nervous system, and the influence of distraction of mind. Equally in both classes of patients may be noticed the coincident general sensitiveness of the nervous system and the family relationship with persons who suffer from various other forms of nervous disorder." E. H. FENWICK (Brit. Med. Jour., Feb. 1, 1902) in an interesting review of this urinary trouble states that recent writers have tended to obscure rather than to clear views which were given us by Paget. He urges the necessity for holding in mind a classification based on the belief that there are two great etiological factors, widely separated, but productive of very similar symptoms, a neurosis which gives true urinary stammering and a stricture which produces false stammering. Fenwick, in considering the pathology and treatment of the first form, states that Paget's view that it never leads to any functional disorders is incorrect; he has seen cystopyelitis and other conditions develop from the severer forms. It is the compressor urethræ rather than the sphincter vesicæ which obstructs the free flow of urine. This can be proven very simply by passing into the membranous urethra a terminal-eyed catheter through which the patient can urinate freely. If the bladder has not become atonied by neglect, free and healthy urination can be permanently secured by tenotomizing the compressor urethræ without opening the urethral tube. This simple operation is done by cutting the membranous region through to the urethra upon the usual grooved guide. That spasm of this muscle rather than of the sphincter is what causes the trouble is further shown by the immediate relief afforded in cutting it and subsequently by the singular "pull" upon the perineal scar just before urination as though the muscle were still endeavoring to close the membranous urethral tube.

Incising, Searching and Suturing the Kidney.—In searching for renal stones, albeit they may previously have been demonstrated and very exactly localized by the X-ray, a very considerable choice exists as to the precise line of incision. H. A. KELLY (Brit. Med. Jour., Feb. 1, 1902) in an address before the New York State Medical Society says that this question as to the best position for incision is at present of maximum importance in the treatment of renal calculi. The whole problem hinges on the character of the renal vascularization. Mr. Broedel of Johns Hopkins has, under Kelly's advice, made a very valuable series of observations on this point. His conclusions are that the kidney is typically supplied by two arterial systems which are completely separated by the renal pelvis. "There is a major system carrying three-fourths of the arterial blood, providing for the anterior and a part of the posterior half of the kidney; and a minor system carrying

one-fourth of the arterial blood, providing for the remainder of the posterior portion. * * * The nearer the surgeon makes his incision in the line which divides these completely separated systems, the less blood is lost. If, however, he strike the major vessels of either of these systems the hemorrhage may be frightful, even great enough to cost the patient's life." It will be seen that there exists in the normal kidney a zone of tissue which is relatively poor in blood. There are certain anatomical landmarks on the surface of the kidney which are easy to find and sufficiently reliable for practical purposes. However, as there is in the undistended kidney rarely a space of more than a few millimeters between the anterior and posterior vascular planes, it is necessary prior to operating to pass a ureteral catheter and distend the kidney with water. This procedure was suggested by Mr. Broedel. Immediately on dilatation the vascular zones separate as much as two centimeters or more, and, if the kidney is cut into while distended, there is less injury to the cortex and the operator is at once made aware of the opening into the pelvis by the sudden gush of water. A third use of the catheter is, of course, that prior to operation one can by irrigation render the kidney relatively clean. The kidney surface is made up of irregular lobules the size of the end of one's thumb. These are bounded by whitish lines which represent the columns of Bertini which extend up between the pyramids. On the anterior surface these white lines coalesce in a longitudinal line, which Kelly proposes to call Broedel's white line. In order to make the incision correctly, one must cut parallel to Broedel's line, leaving about three-fifths of the kidney anterior and two-fifths posterior to the incision. The cut must be extended in a parallel direction to the posterior surface and not angling toward the center of the kidney as one would naturally incline to do. Through such an incision, which is relatively bloodless, both anterior and posterior systems of calyces can be explored. In about two-thirds of all kidneys, owing to irregularities of fetal development, the circulatory distribution is abnormal. In these cases it is usually possible to recognize the anomaly by finding Broedel's longitudinal white line, not on the anterior surface but back, as well as by noting the arrangement of the arterial trunks at the hilum. The kidney may be closed by three rows of sutures, one of fine gut to approximate the pelvis; one series of mattress sutures carried through the entire parenchyma; one, for accuracy only and not absolutely necessary, to closely approximate the capsule.

THERAPEUTICS.

Treatment of Gout.—As the etiology of this disease is still very obscure, it is impossible to place the treatment upon a scientific basis which will fit all cases. Experience, however, has taught that certain methods are invaluable no matter what the cause. M. Heineberg (Med. Times, Feb., 1902) believes that the most rational and most efficient treatment is the regulation of the diet. Elimination of nitrogenous and albuminous principles which result in the formation of urea or uric acid is especially important. This excludes "butcher's meat," also eggs and cheese. Milk, butter, fresh, vegetables and fruits are allowed. Oysters and lobsters can be partaken of moderately and poultry occasionally. Rice, potatoes and sugars are often interdicted by authorities, but may be allowed in reasonable amount. The wines which cause the most trouble are those which contain a considerable quantity of both alcohol and sugar, such as port, sherry and Madeira. Sweet champagnes also quickly produce gout. Whisky seems to have little effect upon the disease. Stout, porter and strong ales are a factor in producing the disease and even beer may have an influence. The drugs which are used in treating the disease strive to eliminate the poison by the kidneys or bowel. For this purpose the various alkaline waters are employed. Colchicum, the classical remedy, is efficient through its action upon the liver. The following combinations of the drug are very good:

℞ Pillulæ hydrargyri,
Ext. rhei,
Ext. colocynth. comp. ..... āā. gr. x.
Ext. colchici acetici ..... gr. xv.
M. Make into 15 pills. Sig. One every three hours till relieved.

℞ Liquor potassæ 3ss
Ext. taraxaci 3i
Tinct. colchici ..... ℥x
Syrupi 3i
Aquæ pimentæ ad 3x
Sig. One dose.

After the bowels have moved thoroughly, give this mixture:

℞ Sod. salicylatis 3iv
Sod. nitratis ..... gr. cl
Pot. iodidi ..... gr. cxx
Vin. colchici rad. ..... ℥xc
Syr. gaultheriæ 3v
Sig. One tablespoonful in half glass of water twice daily for a month.

Treatment of Simple Chronic Bronchitis in Infants.—The treatment of this condition must be local and general. Local treatment, writes J. L. Daguzan (Gaz. hebd. de Méd. et de Chir., Jan. 26, 1902), varies according to the severity of the disease. If the secretion is abundant and obstructs the bronchi, an emetic is indicated; ipecac renders excellent service for this purpose. In subacute cases revulsives are in order; dry cups, tincture of iodine or mustard poultices may be utilized. Vesicatories are on no account to be used. If gastro-intestinal disturbance be present, jalap or scammony in small doses may be given with ipecac. To drain the secretion, balsams are useful—tolu, turpentine or benzoin. The constitutional treatment is of extreme importance. If lymphatism be present, cod-liver oil must be tried; if it be not well borne, prescribe syrup of the iodide of iron or some similar preparation. To rachitics give oil of phosphorus or calcium lactophosphate. Iron preparations are indicated for debilitated children. While tonics are not to be neglected, preparations which are based on alcohol are not recommended. Hygienic treatment should really be considered first. Without a well-chosen diet, substantial and easily assimilated, nothing can be permanently accomplished. During an exacerbation the patient must be ordered to bed. In the intervals sojourn in the country is to be urged. Moderate exercise and massage will augment general nutrition.

ANATOMY AND PHYSIOLOGY.

A New Nutrient Preparation.—As Nature already furnishes the carbohydrates and fats in a concentrated form, the desire for albuminoid foods has resulted in the production of numerous preparations. As a substitute for these a preparation of gelatin is put forward by H. Brat (Deut. med. Woch., Jan. 9, 1902) which he calls "gluton." It is obtained by allowing an acid (HCl) to act on gelatin for several hours at a fairly high temperature, and then neutralizing the same. The filtered product is then steamed, dried, and ground into a fine powder. It is tasteless and readily soluble in cold water. After clinical trials, it is claimed that it is more completely used up than other nutrient prod-

ucts, that it has a higher nitrogen content, is readily digested even in large and continued doses, and can be administered to patients with high temperatures or to those to whom can be given only a liquid diet.

EYE, EAR, NOSE, AND THROAT.

Prognosis in Operations for Glaucoma.—An analysis of 258 cases of glaucoma treated by operation in Hirschberg's clinic is presented by F. MENDEL (Berl. klin. Woch., Jan. 27, 1902). In both acute and chronic inflammatory glaucoma the best results were achieved by iridectomy, successes being recorded in 82 and 77 per cent. of the cases respectively. This operation preserved what remained of sight at the time of operation, and in some instances vision was distinctly improved. Of the total number of cases analyzed (258), 216 were subjected to iridectomy. Twelve cases were treated by sclerotomy, and in 31 instances enucleation was necessary on account of the acute persistent pain. The cases classified as successfully treated by iridectomy were nearly all kept under observation for one or two years following operation. In a few instances the patients were still under observation after three, four, five, six and seven years. While in simple glaucoma successful results were obtained in about the same proportion of cases as in the inflammatory varieties, namely, 75 per cent., only one-half of the cases of secondary glaucoma showed good operative results.

X-ray Diagnosis of Foreign Bodies in Eye.—From a study of 61 cases in which the Roentgen rays were employed, the following conclusions are drawn by W. M. SWEET (Phil. Med. Jour., Feb. 8, 1902). He finds that this method affords the most certain means of detecting and locating foreign bodies in the eye and that this position should always be determined before magnet extraction is attempted. Early extraction is preferable and when the track of the body is through the cornea and lens, its position in the vitreous will indicate whether less damage will be done by removing the metal through the open entrance wound or through a new opening in the sclera close to the indicated position of the body. He believes also that in future more extended use will be made of the large magnet to extract pieces of steel from the vitreous than of the smaller form. Iron or steel which has remained in the eyeball until a fibrocellular covering envelops it cannot be dislodged by the magnet and must be extracted by forceps; this also applies to particles of copper or glass. The employment of normal salt solution to replace any vitreous lost resulted in several instances in eyeballs of good cosmetic appearance.

Tympanic Vertigo due to Obstruction in Eustachian Tube.—Cases of temporary impairment of hearing, tinnitus and history of frequent colds in the head, should have a thorough functional examination, when the lower tone limit will be found to be raised and the upper normal. Reduction of intratympanic pressure permits undue compression through the ossicles of the membranous labyrinth and consequent vertigo. These cases BRANDEGEE (Archives of Otology, Vol. xxx., No. 3) relieves by use of the gold electrodes of Duel applied in a careful manner and followed by catheterization. He cites three cases which in this way were relieved completely of their vertigo.

Mydriatics in Refraction and in Asthenopia.—While mydriatics are not necessary in all cases they are in very many cases. What these cases are DR. RISLEY (Ophthalmic Record, Jan., 1902) determines as follows: The emmetropic eye, he found in examination of large numbers of school children, gave best vision. Variations from emmetropia gave not only asthenopia, but also varying degrees of fundus oculi changes, all the result of eye-strain. Knowing this he claims that the prescribing of correcting glasses "is not the function of the optician, and should not be lightly assumed by the ophthalmic surgeon." The problem of prescribing the proper correcting glasses is not simple, but complex, the complexity being due to the requirements for comfortable binocular vision, *viz.*, harmonious relation between accommodation and convergence, excessive accommodation being required in hypermetropia and excessive convergence in myopia. There is a physiological range in most of these cases within which either one of these can be used independently, *i. e.*, the accommodation being "relaxed in the interest of single vision, or convergence abandoned in the interest of a clear image at the macula. . . The struggle to maintain binocular clear vision is the cause of the asthenopia and its associated pathological conditions." The author claims that a mydriatic is necessary in many of these cases to rest the function of the eye and restore a normal behavior of the fundus tissues before a healthy eye is obtained to judge of the exact quantity of the refractive correction needed. The fixed cramp of the converging muscles in hypermetropic cases gives false testimony even with the ophthalmometer unless the prolonged use of a cycloplegic has been tried in a large number of these cases. In myopia, also, the fundus changes can be relieved only by a cycloplegic, sufficient to justify the proper judgment of correction.

OBSTETRICS AND GYNECOLOGY.

Fever During the Puerperium.—Every case of fever during the puerperium should be regarded as septic, writes J. F. MORAN (Amer. Jour. Obstetrics, Feb., 1902), until this is positively excluded by a most careful and painstaking examination. Other conditions with fever which are sometimes overlooked are phthisis, malaria, typhoid, influenza, pneumonia, and the exanthemata. Any genital indication should be followed up by thorough bimanual and specular examination, and, if possible, by bacteriological and microscopical examination. One of the most common causes of fever is intestinal toxemia. Following labor there is a semiparesis of the bowel, favoring fermentation and decomposition therein, and the fever subsides after catharsis.

Cervical Metritis.—This is a very common condition and the forerunner, as a rule, of trouble higher up in the uterus. A. DOLERIS (La Gynéc., Dec. 15, 1901) concludes an article on this subject as follows: Caustics are efficacious in treating recent ectropions and endocervicitis of superficial character. The strong caustics are not preferable to a series of other topical applications, which are less energetic, more penetrating and very antiseptic, and which combined with glycerin act very rapidly and simply. Such are the essential oils, creosote, tincture of iodine, ichthyol, etc. In treating the scars due to ulceration or cervicitis, caustics of all kinds have only a temporary and doubtful action. Here the knife is very much better, because it removes the diseased tissues as widely and as deeply as is necessary.

Diabetes and Pregnancy.—Perhaps the most common, and at the same time the least disquieting, abnormality of the urine during gestation is glycosuria, or, rather, lactosuria, resulting from an absorption of milk-sugar from the functionating mammæ. On the other hand the coincidence of true diabetes and pregnancy is an event of extreme gravity, which demands immediate recognition and stringent treatment. The rarity of this latter condition, its importance from a diagnostic standpoint, and the difficulties in its treatment, all make the recent paper of DR. ERNST'S (Edin. Med. Jour., Feb., 1902) a contribution of great interest. Diabetes is commonest between the ages of

forty and sixty, a period of life which is well without the limits of the childbearing period; indeed, two-thirds of the cases do not begin until after the menopause. When the disease does occur in a woman of childbearing age, it usually suppresses menstruation and may even produce atrophy of the uterus. There is, however, a small percentage of these cases in which menstruation continues; such patients may become pregnant, and even repeatedly pregnant during the course of the disease. It is a well-known fact, however, that the severity of diabetes is very much greater in young subjects than in old, hence those diabetic women who are still capable of becoming pregnant usually exhibit a dangerous form of the disease. The pregnancy supervening upon this condition tends, as do all other forms of severe physical strain, to aggravate it and to hasten its progress. There is another possibility through which pregnancy and diabetes may become associated, namely, that a pregnant woman may become diabetic. In such cases the prognosis is much more favorable. The condition begins to improve within a few days or weeks after delivery, although the disease may recur in subsequent pregnancies. The diabetes may persist in mild form in the intervals between pregnancies and may disappear after the menopause, or it may become progressively worse and take on a grave aspect. The effects of the diabetes upon pregnancy and childbed are extremely deleterious. Intra-uterine death of the child, with its variable train of results, has occurred in about two-thirds of the cases. Hydramnios is a frequent complication. As regards the woman, the lying-in may proceed normally, whether the diabetes improve or not. On the other hand, death may supervene in the same manner as after operations or injuries in such cases, with the symptoms of coma and collapse. The obstetrical management of diabetes with pregnancy is evidently a very difficult problem. The author believes that the termination of the pregnancy, and that, too, at the earliest possible date, is the only course which can logically be followed. In the first place, the chances are two to one that the child will die *in utero*, hence its life is not of great account. But it is unwise passively to await this event, since the prolongation of the pregnancy materially weakens the chances of the mother. The liability to death from collapse after delivery is in direct ratio to the age of the fetus. For these reasons, the procedure advocated by the author seems wise and conservative.

Tubal Pregnancy.—In the eleventh century Albucasis described the first known case of extra-uterine pregnancy. In 1875 Dr. Thomas was the first to operate for the relief of the hemorrhage attending the rupture of a tubal sac by boldly thrusting a galvanocautery through the vaginal wall, removing the fetus and thoroughly cleansing the cavity with a carbolic-acid solution. Dr. Tait instituted as a routine practice the treatment of this condition surgically. T. GOODRICH (St. Paul Med. Jour., Feb., 1902) points out that nearly all pregnancies are probably extra-uterine in the beginning. Both the cilia in the Fallopian tube and the uterine cavity move toward the cervix and the spermatozoa work their way upward against this current. Spermatozoa are frequently found free in the peritoneal cavity. The cilia extend a short distance beyond the tubal opening and sweep the ovum into the tube as soon as it escapes from the follicle. The tube, however, is long and covered by delicate plications and deviations, so that the progress of the ovum is frequently impeded. Should any cause be sufficient to stop its progress, it may either die or become attached to the mucous membrane and develop. Factors in the causation of this condition, therefore, may be easily understood: (1) A congenital narrowing of the canal. (2) A large or unusually shaped ovum, hydramnios, twins, encephalocele, etc. All primary deformities in the ovum have been noted in ectopic gestation. (3) Disease of the Graafian follicle so altering the membrana granulosa as to make it more adhesive to the tube. (4) Excessive involution which has affected the tubes as well as the uterus. This is considered an etiological factor in isolated cases from the fact that the condition is much more rarely met with in multipara. (6) A tumor of the uterus or ovary distorting or closing the lumen of the tube. (7) Most authorities believe that inflammations of the appendages or pelvic structures are the casus belli in many cases, and the gonococcus is perhaps the most frequent invader. On the other hand, ectopic gestation seldom appears with double pus tubes, probably because the pus kills the spermatozoa. The treatment of these cases in their various phases is distinctly surgical. If surgical interference were withheld in all instances only five per cent. would recover, but in the hands of a skilled surgeon the mortality-rate is less than one per cent. The time for operation may be questioned. Shock from hemorrhage is seldom a contraindication. If the condition be recognized before rupture or if hemorrhage cease and a hemotocele form thorough preparations should be made for an aseptic operation. In the tubo-abdominal variety when the eighth month has passed, some advise the postponement of operation until pains begin. The author believes in such instances the mortality is least when celiotomy is deferred at least four or six weeks after false labor has taken place, thus allowing time for separation of the placenta, which can be more readily removed without alarming hemorrhage.

Faulty Uterine Growth.—The uterine ligaments play a considerable rôle in cases of faulty development of the uterus, according to D. H. CRAIG (Boston Med. & Surg. Jour., Feb. 13, 1902). The round ligament begins to be important in early fetal life. Its development proceeds *pari passu* with that of the uterus, tubes and ovaries. Any factor influencing the development of the uterus will influence also that of the round ligament. Experience has shown treatment of faulty prenatal uterine development to be futile. Cases of faulty growth (growth being defined as postnatal change) comprise two classes, as follows: (*a*) Inhibition or absence of growth; (*b*) tardy or delayed growth. In the former class the uterus maintains the infantile characteristics of long cervix, small body, anteflexion. In the latter a certain amount of growth has occurred, but at puberty growth has failed; the body of the uterus, however, is as long as or slightly longer than the cervix. In the case of infantile uterus prognosis is very doubtful; in the other class of cases treatment is of value, but must be continued for a period varying from nine months to two years or more. Treatment begun at fifteen to seventeen years of age promises better results than that which is begun after marriage—say at twenty-two years. An important factor in examination is the uterine probe. If the cervical canal in the least exceed that of the body a most unfavorable prognosis is the only one justifiable. Treatment must be general and local. Out-door life, gymnastics, Swedish movements, etc., are indicated. Iron seems to be valuable even when there is no anemia; presumably its action is due to its power to increase the blood supply to the pelvis. Active and not passive local congestion is required. The ordinary means of obtaining it are intracervical application of impure carbolic acid, negative galvanism, faradism, hot douches. In obstinate cases discission may be practised; it appears to induce growth, just as a laceration of the cer-

vix causes overgrowth. When growth begins in response to treatment, only to cease after a little while, the retrogression may be due to sagging of the uterus and resulting passive congestion. The indication is plainly to support the uterus from the start. For this purpose Craig recommends a small soft or hard rubber retroversion pessary; the smallest pessary that will do the work should be used.

THERAPEUTIC HINTS.

Pharyngitis and Acute Bronchitis.—In laryngitis and acute bronchitis, Liègeois prescribes the following:

℞ Sodii benzoat.....gm. 4.0 (ʒi)
Tinct. aconit.....c.c. 1.20 (ɱxx)
Aq. laurocerasi..... 4.0 (ʒi)
Syr. tolutani.
Syr. codeinæ.
Aquæ .....aa. 60.0 (ʒij)

M. Sig. To be taken in the twenty-four hours. For pharyngitis he gives large doses of sodium benzoate.

Infantile Syphilis.—Attempting to medicate the newly-born by mercurializing the mother, or goat or cow which is supplying milk to the infant, is useless, writes H. de Rothschild (Le Progrès Médical, Dec. 7, 1901). By the alimentary tract one may give Van Swieten's solution in milk in doses of 20 or 30 drops a day during the first month and 40 to 100 during the second, third and fourth months. The solution is as follows:

℞ Mercuric bichlor. corros..... 1.0
Alcohol 100.0
Aquæ 1000.0

Twenty drops would be equivalent to gm. 0.0025 (gr. 1/26) of the mercury salt. The protiodide, in doses of gm. 0.01 (gr. ⅙) a day, may be substituted for the bichloride. The cutaneous method, however, is the surest and most prompt. Five minutes' daily friction may be made with gm. 1.0-2.0 (gr. xv-xxx) of mercurial ointment, changing the site of application each day to avoid irritation of the skin. Have the part well washed with soap and hot water before the rubbing, and give the child a bath every second day. An excellent method of applying mercury is by the sublimate bath administered once or twice a day, each bath containing gm. 1.0-3.0 (gr. xv.-xlv.) of mercuric bichloride.

Vaginismus.—The general treatment consists of avoidance of intercourse, change of air, sea-bathing, exercise, and warm alkaline baths of soda and starch, using a bath speculum in the vagina. A stimulating diet should be avoided, and bromides with valerian or valerianates administered. The local treatment may consist, first, of warm vaginal washes of bichloride of mercury, 1 in 5,000, tincture of opium, 1 in 120, chloral, gm. 1.0 to 2.0 in 500 c.c. (gr. xv.-xxx in Oi), liquor plumbi subacetatis, 1 in 240, or tincture of calendula, 1 in 20; second, of suppositories of cocaine, gm. 0.12 (gr. ij), morphine, gm. 0.06 (gr. i), extract of belladonna, gm. 0.12 (gr. ij), extract of hyoscyamus, gm. 0.7 (gr. x.), or iodoform, gm. 0.35 (gr. v.); third, of lanolated creams of cocaine, 2 to 4 per cent., extract of belladonna, 2 per cent., morphine, 1 per cent., atropine, gm. 0.12 in 30.0 (gr. ij-ʒi), iodoform disguised with coumarin, vasol, iodine or ichthyol. The warm vaginal douche, with alkaline, sedative or astringent lotions added, may be used night and morning. Medicated glycerin tampons or a vaginal dilator may be worn at night. Direct application to the parts of lunar caustic, carbolic acid, solution of silver nitrate or cocaine may be made. If these means fail, operative dilatation must be resorted to.

Lumbar Puncture.—Of sixty lumbar punctures practised by A. Chipault (Le Médecine Moderne, Dec. 25, 1901) for therapeutic effect, fluid was not obtained in nine; of the others cure resulted in eleven cases, improvement in fourteen, and in the rest the results were negative. The cases cured were serous hypersecretion in congenital hydrocephalus, coma in an old syphilitic, grippe, meningitis, choreiform movements, specific meningomyelitis, septic meningitis, cranial traumatism and vertebral traumatism. The improved cases were two of hydrocephalus, two of infantile cerebellar tumors, pneumococcus meningitis, five of tuberculous meningitis, two of epilepsy, uremia with profound torpor, and rheumatism with rachialgia. In all these cases except the case of rheumatism, the improvement was only temporary. The cases with negative results were nine cases of hydrocephalus, four of tumors, three of tuberculous meningitis, one of cerebrospinal meningitis, three of epilepsy, four of general paralysis, blindness with papillary edema, and vertebral fracture.

Tuberculosis.—At a clinic given by Dr. J. E. Stubbert of the Loomis Sanitarium (Post Graduate, Nov., 1901), he advised special care of the alimentary canal and the blood. Chronic gastritis and dilatation of the stomach are very common, but one must not be misled by a temporary upsetting of the stomach from cough syrups, creosote, etc. The treatment is, first, lavage two or three times a week, and, second, the Einhorn electrode. The diet at first should be liquid or semisolid. Secondary anemia is the common blood condition and is most satisfactorily treated by arsenic and iron. Blaud's pills, chloride of iron, peptomangan, Fowler's solution, arsenauro and arseniated hemaboloids are of value. Static electricity is another good general tonic. For the cough do not give sweet vehicles and avoid morphine if possible. Two or three doses a day of codeine, gm. 0.015 (gr. ¼), or heroin, gm. 0.005 (gr. 1/12), will gradually bring the cough under control. Of inhalers the Underwood hot-air inspirator, used once or twice a day at 300° to 400° F., has its advantages. The following are good solutions to use with it:

℞ Ol. camphor.....gtt. clx
Terebene.
Eucalyptol .....aa. ad 30.0 (ʒi)
Dose: Two to ten drops.

℞ Creosoti .....8.0 in 30 c.c. (ʒij in ʒi)
Thymol .....0.25 in 30 c.c. (gr. iv. in ʒi)
Eucalyptol.
Ol. pini sylvestris.
Ol. gaultheriæ.
Ol. menth. pip.
Acidi benzoici.
Dose: Two to eight drops.

℞ Tinct. hyoscyami .....gtt. L in 30 c.c. (ʒi)
Tinct. iodi.
Ol. pini sylvestris.
Menthol.
Alcohol.
Eucalyptol.
Dose: Five to ten drops.

But the multinebulizer is much better for general use. Solutions adapted to it are:

℞ Menthol.
Camphor .....aa. gm. 1.0 (gr. xv.)
Albolene..... .....ad. 30.0 (ʒi)

℞ Creosote .....c.c. 4.0 (ʒi)
Albolene .....ad 30.0 (ʒi)

℞ Alcohol, 75 per cent.
Glycerin.

For two or three hours after the use of either of these inhalers the breath gives the odor of the drug used, showing that the bronchial mucous membrane must have been tolerably well saturated.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 Fifth Avenue, New York.

SATURDAY, MARCH 8, 1902.

SOME NEW PHYSIOLOGY.

Not all of the revolutionary and far-reaching advances in biological science are heralded as such by their promoters, for some grow into their importance almost imperceptibly, yet very rapidly, the labor of so many different minds and hands that no one of them can say, "This new doctrine is my own." Of such nature is the development, still doubtless only beginning, of the theory of ionic dissociation and its new hypothesis of life, with all its varied promise to the physiologist, the therapeutist, the bacteriologist, the pathologist, and the surgeon. This new movement is one more example of how important truth, about to become clear, hovers, as it were, in the very atmosphere around the body of interested researchers, however widely scattered spatially, its component parts issuing one by one from the minds of many such, and then uniting quickly to form a vast new star to light a world of doubt.

One thoroughly familiar with the American, English, and German physiological literature of the last five years will recall articles reporting the demonstration of certain facts and principles apparently as unrelated as they are various. One of these proved that the hearts of animals high in the zoölogical scale, if properly cared for, will continue their normal rhythmic beating long after all the nerves connected with them have been severed; this was a surprising thing, for it demonstrated that, whatever nervous influences may do, they do not cause or even occasion muscular contraction. Another research proved that mammalian hearts, even when taken out and isolated completely, would beat for hours when provided with a proper nutrient solution irrigated through them, this nutrient solution being blood serum. Another showed the absolute necessity of certain inorganic salts in the nutrient solution for the normal acting of protoplasm, in particular of muscle and of nerve. The dependence of the mysterious process of blood coagulation on the salts of calcium became certain at about the same time. Meanwhile, another experimenter was making interesting studies on the nature of colloids, and had worked out to demonstration in what ways an electric current causes the gellation or coagulation of hydrosols into hydrogels—of which class protoplasm is a member—and physics had added one more and a large element to the understanding of what was once termed "vital force." Still another research discovered and demonstrated that the normal rhythmic movements of protoplasm under abnormal experimental conditions were possible only in electrolytes, that is, in solutions capable of conducting appreciably an electric current whether galvanic or static in nature. Now then, by this important observation there came into adaptation to physiology a doctrine well known for many years to the physicist and the chemist, namely, the theory of electrolytic dissociation and the underlying doctrine of the ions.

This, then, was the rational conclusion to this complicated but straightforward series of proven propositions: the movements in and of living protoplasm take place apparently by means of ions, the electricity-bearing portions into which molecules break down when in solution, and the energizing principle of living protoplasm at last appears in very truth to be electricity. This proposition every physiologist has long had in mind inevitably as he saw measured in his capillary electrometer the "action current" in the beating frog's heart and the electric current known as the "negative variation" which may be conducted away from the injured nerve or muscle or gland or eye of any recently-killed animal. It has, indeed, been for a century the natural presumption to all familiar with the phenomena of the nervous system, but authority had by its denial (as so often) made it doubtful as a scientific

proposition, concealing it beneath the generally-adopted thermodynamic hypothesis. Electrical phenomena in the lives of many sorts of animals and even of plants are so numerous and so well known that they need no suggestion here. At last, with the cellular methods of the twentieth-century biology, the electrical basis of protoplasmic energy bids fair to be established.

Supposing now, for the sake of explanatory argument, that the inherent energy of living tissues is indeed, for the present at least, really classifiable as electric, what then is this doctrine of ionic dissociation on which the supposition rests? What, too, is the probable practical outcome of the theory in the directions for which the medical profession in particular has its being, in the alleviation of animal disease and pain? What is all this to medicine as an art, inseparable always from medical science? Thus far in the development of this new knowledge the practical bearings seem to be in relation only with the ionic doctrine and not much with its important corollary that the motive power of life is essentially electrical. What then, very concisely, is the theory of ionic dissociation, biologically applied? It is all too new as yet for important practical results, and a widespread interest in and acquaintance with the theory must precede the more particular researches.

Atoms and molecules long since have become to the student of chemistry and of physics objects as real as chairs and mortgages—one believes in them because a multitude of various facts and theory all point conclusively to their existence, and quite refuse to be explained by any other supposition known. We believe in atoms and in molecules, in other words, because our reason bids us inevitably to do so. Just as universally, without a doubt, will the students and scientists of the next ten years believe in ions and in their laws, and will discuss them and experiment upon them as they do with bacteria or leucocytes. In the uttermost of its simplicity, then, the ionic doctrine may be given in syllabus as follows: The molecules of salts, acids, and bases when they are dissolved in a liquid break up into ions, this solution being then called an electrolyte, for it will conduct a current of electricity. The liquids which have not the property of dissociating molecules into ions cannot conduct an electric current, and liquids which have the property are non-conductors unless ions are present in them to serve as bearers of the electrons or electric changes (for example, 1 c.c. of the purest water ever prepared was found to have a resistance to a galvanic current equal to 25,000,000 miles of copper wire 1 mm. in diameter). According to Arrhenius, the conductability of an electrolyte is proportional, for a constant difference of potential, to (1) the number of ions, that is, to the number of dissociated units, in the solution; (2) to the relative electric charge of these ions, and (3) to the speed of the ions. The proportion of the dissolved molecules which break up or dissociate into ions depends, within limits, on the degree of the dilution of the solution; a certain definite dilution, however (distinct for each solvent and for each dissolved substance), dissociates completely all the molecules, and further dilution merely separates the ions further from each other. Water is the best dissociator of molecules into ions; formic acid appears to be the next best, dissociating three-fourths of the molecules dissolved; nitric acid comes next, perhaps, then methyl alcohol, dissociating one-half to two-thirds the molecules; ethyl alcohol is not so good a dissociator as methyl alcohol, while acetone, the ethereal salts, and the hydrocarbons come in order, the last having only feeble power in this direction. Organic compounds are much less dissociated than are inorganic salts, and the ions are more complex, and less understood at present. In the presence of static or galvanic electricity certain ions take on each a positive charge of electricity and are then termed cations while the other ions (of a molecule dissociating into only two ions) acquire negative charges or electrons and are termed anions. If the poles of a battery be introduced into an electrolyte, the cations or positive ions go to the cathode, which is the negative pole, and the anions or negative ions go to the pole which is positive and called the anode, according to the universal law of electrical attraction and repulsion. Ions may be single atoms or groups of atoms; cations are more apt to be single atoms than are anions. The cation of all acids is the hydrogen; the anion then varies with the acid (*e.g.*, NO_3, SO_4, CO_3). The anion of bases is the hydroxyl group (OH); the cation varies with the base. In the case of salts, both the anions and cations vary with the salt, depending on the acid and base which had combined to form the salt. All atoms have either the same capacity for electricity or a simple multiple of the capacity of univalent atoms, that is, a bivalent atom or ion will carry twice as much electricity as an univalent ion, a trivalent ion three times as much, etc., which is "Faraday's law." The capacity for thermal energy is the same for all atoms.) Ions actually move through

the electrolyte, and not merely transfer their electrons; with a moderate strength of current Kohlrausch calculated that the velocity of a hydrogen ion was 0.0032 c.m. per second, most other ions moving much more slowly. The amount of electricity necessary to charge a liter of an electrolyte containing dissolved as many grams of a univalent metal as there are units in its molecular weight ("its electrochemical equivalent") is for all substances studied 96,537 coulombs—a very considerable charge for every ion; yet a bivalent ion would carry twice as much, a trivalent ion three times as much, and so on up to the octavalent ion, which is the highest valence known. (From this it appears what a very large amount of energy certain ions may carry, and the answer to several problems is herein suggested. Whether or not an ion is a cation or an anion is a relative matter, for a cation may become an anion in a complex salt when some other element is present which is stronger electrically than itself. An ion having the same chemical composition may carry different electrons under different conditions, *e.g.*, of origin.

These concise statements bearing on the ionic theory (taken mostly from the books of Prof. H. C. Jones and from Hollard) are intended to convey the chief principles of the matter, which is obviously not at all difficult to understand. Works on the theory are now accessible to any student of medical science who would know more systematically as to the physical chemistry of this now important doctrine. Next, it will be interesting to review briefly some of the actual medical knowledge based on this theory and derived through its application to these doubtful problems of physiology and therapeutics.

In the first place, it must be obvious that protoplasm (constituting of course all the tissues of a living body) is an electrolyte of the most perfect sort, it being practically a watery solution of considerable dilution of various salts, acids, and probably bases. Sodium chloride is especially important among the salts dissolved in the protoplasm, its ions being the univalent positive sodium and the univalent negative chlorine. The bivalent negative group CO_3 is also conspicuous, while in the blood plasma the univalent cations sodium and potassium and the bivalent cations (positive) calcium and magnesium and the univalent anions chlorine, hydroxyl, and HCO_3, and the bivalent anions HPO_4 and SO_4 are especially abundant. Each of these, and numberless other sorts, of ions is capable of carrying a constant charge of electricity proportional in each case to its valency in chemical combination; each, too, is capable of instantly overcoming the electrical nature, positive or negative, of any ion with which it comes into relation. The nature, number, and location of these ions depend on chemical metabolism in the cell, which of course is in turn dependent on the composition of the blood, which is likewise subject to the conditions imposed by the quality, quantity, absorption, and digestion of the food of the animal. The metabolism in the cell, consequence of the ingested food, liberates energy certainly in the form known as heat, but quite as certainly, according to this theory, the motor energy of the body is that of the ions powerfully and changingly charged with electricity, and continually passing to and fro, loading and unloading their work—performing charges of electricity. As already hinted W. B. Hardy has shown that protoplasm may be considered a reversible hydrosol or colloid, consisting of particles in suspension in water containing many dissolved salts and probably acids and bases. These particles appear to be aggregations of from 1,000 to 10,000 molecules, each having around it probably a double layer of ions heavily charged with opposite electricities. The proteid molecule especially is very large and the particles correspondingly labile. It is the repulsion between the particles which perhaps prevents their precipitation. Here, then, is a condition of equilibrium easily disturbed, especially since the particles are made up of molecules so large and unstable as those of muscle and nerve and epithelium, and this disturbance means a powerful discharge of energy. Every "particle" of the hydrosol protoplasm is then practically, according to this hypothesis, a minute but relatively potent Leyden jar charged with static electricity and discharged by the accession of ions having a sign opposite to that of the internal of the two layers about the "particles:" this sign appears to be usually negative. This is the physics at the basis of many protoplasmic changes and effects according to this hypothesis, and so strong is the evidence that the probability of its truth is considerable.

One more precise development from this combination of new ideas on protoplasm and the ionic theory has been worked out and in outline set forth by Dr. Albert P. Mathews. Working with the methods of the pioneer Jacques Loeb, he has probably developed and announced the essentials of the nature of the nervous impulse, one of the most interesting puzzles in all physiology. This research has been printed only in abstract and in a brief article in the *Century* for March,

the latter of which we may summarize as follows: When an electrolyte stimulates a nerve, *e.g.*, the sciatic of a frog, placed in it, it does so by withdrawing part of the water in the neural protoplasm. In such electrolytes it is not the positive ions (cations) which stimulate, but the anions or negative ions—for instance, the chlorine ion dissociated from the sodium ion in the case of normal saline solutions. It appears however that it is not strictly the ions themselves which stimulate the nerve, but rather the electrons which the ions carry; it seems to be electrical energy and not merely chemical energy by which nervous tissue transmits its impulse, although, thinks the author, these two are probably identical in reality, all chemical affinity being probably a phase of electrical attraction. The positive ions or cations tend to destroy irritability, inhibit action, the effect being roughly proportional to their valence or the number of electrons which they bear. We may therefore counterbalance the inhibitory influence of the cations by supplying anions or negative ions of sufficient charge or power, and thus produce stimulation of the neural protoplasm. This stimulation of the nerve consists probably in the partial precipitation or gellation of the colloid, or reversible hydrosol, which all tissue is (as already noted). This progressive precipitation or clouding may in some organisms be seen with the eyes, and was actually observed and described many years ago by Darwin (that wonderful observer!) as the stimulating wave slowly passed through a tentacle of Drosera. The nervous impulse consists, then, in the passage of the colloids of the nerve toward or to gellation, a conclusion, as Mathews states, simultaneously reached in regard to muscle by Loeb. "The colloidal particles are positively charged. Those charges induce in the water about each particle negative charges, the number of negative charges being proportional to the surface of the particles. Now, when two adjacent particles are thrown together mechanically (mechanical stimulation) or by heat or in any other way, they coalesce, and the surface of the coalesced particles is smaller than the sum of the surfaces in the separate particles. There is a sudden diminution in the number of positive charges holding the negative charges. A certain number of the latter are at once set free. These immediately precipitate the next layer of colloids. By the coalescence of these particles, negative charges are again liberated and the nerve impulse is thus propagated. The speed of its propagation is problably connected with the minute diameter of the axis cylinder process, which makes the movement take place in one direction. If we prevent precipitation we can stop the nerve impulse and the negative variation also. Thus, anesthetics probably prevent conduction in nerves by dissolving to some degree the fatty substances conspicuous in nervous tissue, thus preventing the progressive gellation which conduction requires.

Dr. Jacques Loeb in his last published article (*American Journal of Physiology*, February, VI., 6, p. 411) similarly works out some of the applications of the new ideas to toxins and antitoxins. Already he had suggested and studied the probable cause of the action of muscle, as already noted. Starting with the now familiar notions concerning the probable structure of protoplasm, Loeb maintains with much good evidence behind him that toxic and antitoxic effects may be due to the various alterations in the viscosity of the protoplasm making up living tissue. He considers the process of cell division one of the phenomena of protoplasmic streaming, and it is obvious that oftentimes the action of toxins and antitoxins may be directly dependent on division of cells. Whatever, then, disturbs the streaming power of protoplasm will interfere with toxins and antitoxins, for to alter the normal viscosity of a colloid is of course to disturb this reproductive power. Supposing, for example, a toxin to be dependent for its effects in the body on the activity of a large number of monovalent anions, their evil influence would be easily controlled by the introduction of even a small number of bivalent cations, since bivalent anions have double the power that univalent ions have; and employing the ions of much higher valence (many of the most violent poisons are such) the effect would be still more practicable owing to the smaller amount of the substance required. Such results are already demonstrated for low organisms in the laboratory; it remains to apply the principle to the massed cells of more highly developed animals.

So as concerns antiseptics, enlightening conceptions, explanatory if not prophetic, are not lacking. The reason that salicylic and picric acids, *e.g.*, are so destructive to low forms of life is that they are easily dissociated in the tissue electrolytes and thus liberate a large proportion of hydrogen cations, which are preëminently poisonous, for reasons already suggested. Similarly for mercuric bichloride, the mercury cations are very poisonous, while the copper in its solutions is nearly as effective. Metallic salts in general disinfect, that is, kill, not only in proportion to

their concentration, but also according to the special properties of the salt and electrolyte concerned. The bactericidal power depends both on the metalic cation and the anion and on the proportion of undissociated molecules. When the salt is a complex one the metal may be then only a part of a compound ion and so it may act much differently from what it would alone. An example is the potassium of potassium ferricyanide. Ions of high valence are the most strongly disinfectant, bivalent less so, and univalent ions least, other qualities being similar; for example, fluorine, bromine, and chlorine are active in this respect in the order given, the order of their descending valences. The effects toward disinfection of salts with a univalent cation are due to the negative electrons of their anions. Loeb also demonstrated that for muscle the relative toxicity may be proportional to the migration-velocity of the ions.

Such are, in merest outline, the methods by which some of the results already attained by this new sort of knowledge have been secured. The future will reveal their value, whatever it be, to science and to mankind. The present line of research has evidently but just begun, and has apparently not yet reached what one may hope will prove the most practically useful field of all, the scientific preparation of drugs for the cure of human disease.

AN OPPORTUNITY.

It is a surprising bit of information, but none the less true, that at the present moment there is not a single bed in any hospital in New York City so endowed as to be free for the occupation of a trained nurse. So many well-to-do patients have appreciated and not failed to expresss their sense of gratitude for unselfish nursely devotion in serious illness that it seems almost incredible that some of them should not have been prompted to make arrangements so that nurses themselves may have the opportunity to benefit by the best care when they fall ill. As a rule, of course, nurses locate in the place where they have had their hospital training. These have a recourse in illness, but at times they move to another city or a change in hospital management makes their former training-school practically a strange institution and then they may well feel the need of hospital care without being able to obtain it as they should. This situation presents an opportunity for practical charity of the most benevolent kind that should not be neglected.

Perhaps more than anything else the institution of the trained nurse has in recent years reduced the death-rate from disease and lessened the sum total of human suffering. Like the physician himself, she is the butt of many jokes when people are well, but a precious source of consolation and an assurance against worry when there is sickness in the household. Her greatest mission has been the prevention of secondary illness in families by lifting the load of responsibility for the care of the sick that used to weigh so heavily, especially upon female relatives. Surely others should be mindful of her and provide for at least the removal of the burden of personal responsibility when, in her turn, she falls ill.

THE ANESTHETIC FOR CHILDREN.

The discussion on lymphatic enlargements in children and the problem of their removal under an anesthetic with the danger involved in the use of chloroform, especially in cases in which the lymphatic constitution exists, precipitated as an interesting side issue at the last meeting of the Section on Pediatrics of the New York Academy of Medicine the question as to what anesthetic it is safest to employ in children.

There is no doubt now that most of the deaths in chloroform narcosis, in children at least, occur in individuals who are the subject of the lymphatic diathesis. The records of the children's clinic at Gratz for the last twenty years show that in every case of fatality with chloroform as an anesthetic the autopsy revealed the presence of the lymphatic hyperplasia which is the principal feature of the so-called *constitutio lymphatica.*

Reports from many other clinics are of the same general tenor. So much so that, as Dr. James Ewing said, the question among pathologists now is not, Does the lymphatic constitution predispose to death under chloroform? but rather, Does death under chloroform, in children at least, ever occur apart from the lymphatic constitution? Dr. Ewing's personal experience and the reports sent him of autopsies for deaths under chloroform show that in America the conclusions from the Gratz observations hold good. It seems probable, however, that chloroform does not enjoy the unenviable distinction of being the only general anesthetic that is liable to cause death in these subjects. Dr. Lartigau's report of experiences at Roosevelt Hospital shows that autopsies on children affected by the lymphatic constitution came after ether anesthesia as well.

There is no doubt, then, that in every case in

which it is determined to use general anesthesia in children a careful examination should be made for any and all signs of the existence of the lymphatic diathesis. The symptoms are not difficult of recognition. The presence of universal enlargement of the lymph-nodes, without direct inflammatory cause: hypertrophied tonsils and adenoid hyperplasia, with the tendencies to anemia, weakness of pulse and fluttering heart that may accompany insufficient development of the heart and large blood-vessels, all are pathognomonic of the lymphatic constitution. It is not necessary for all of these symptoms to be present, but a combination of some of them with perhaps the physical signs of a persistent thymus and a history of delicacy of health are sufficient to arouse suspicion. Death from chloroform is too serious a danger to be risked if the case is clearly not in the category of those free from constitutional lymphatic tendencies.

It is in operations upon parts requiring deep anesthesia that the special dangers of the administration of anesthetics develop. It is in these cases that fatalities are apt to occur. It is clear, then, that it is at least tempting fate to use general anesthesia for operations upon the tonsils or upon adenoid hypertrophy.

It seems probable, however, as stated by Dr. Jacobi, that in general chloroform is the most favorable anesthetic for children. Chloroform, when fatal, produces death through the heart and the heart of the child has proportionately to the body weight much more force and is less susceptible to inhibitory influences than in the adult. Moreover, children's hearts are seldom crippled by valvular cardiac disease. Children's respiratory apparatus and kidneys are even more susceptible than are those of adults to the evil effects of ether. Unless some cardiac lesion exist to contraindicate it, or unless there be suspicion of the existence of the lymphatic constitution with its almost invariable accompaniment—an undersized heart and aorta, chloroform is then the anesthetic of choice. Much of the present objection to the use of chloroform due to the occasional deaths that occur from it will disappear if careful search for any signs of the *constitutio lymphatica* be made before the anesthetic is administered.

ECHOES AND NEWS.

NEW YORK.

Red Cross Hospital Work.—The State Board of Charities has granted permission to incorporate to the New York Red Cross Hospital, the Associated Charities of Syracuse and the Emergency Hospital of Buffalo. It is likely that the new Red Cross Hospital will be erected on the West Side, in the vicinity of One Hundredth Street.

Compulsory Vaccination Bill.—The Compulsory Vaccination bill, which passed the Senate with no opposition, and is now in the Assembly, encountered opposition Monday last at the hands of Dr. Lewis, State Health Commissioner, and Dr. A. G. Root, who represented the New York State Medical Society. They told the Governor that the bill was too far-reaching in its provisions.

Compulsory Vaccination.—Health Commissioner Ernst J. Lederle, E. Eliot Harris, M.D., and Daniel Lewis, State Commissioner of Health, will meet early this week to consider the Compulsory Vaccination bill which is now before the Legislature. It is understood that the bill is not favored by the Health Commissioners, on the ground that many persons who would otherwise be vaccinated would refuse if it were made compulsory. From 25,000 to 35,000 vaccinations are now performed free each week by the Health Department.

Private Smallpox Hospital.—The crying need for such an institution seems to be meeting with some recognition. It is known that last year Mr. Carnegie offered $500,000 to the Minturn Hospital for a private pavilion. It is to be regretted that the way was not clear at that time to accept this generous offer and the city of New York is the poorer for a lack of initiative on the part of the Board of Managers. The deficiency should be remedied and that quickly.

Smallpox Hospital for The Bronx.—As amended by the Committee on Cities, the bill introduced by Senator Hennessey authorizing the construction of a $500,000 hospital in The Bronx will provide that borough with a building for the reception of smallpox cases. The bill was reported favorably to the Senate on Wednesday last, with amendments suggested by Dr. Lederle, Commissioner of the Health Department. It authorizes the Commissioners of the Sinking Fund to acquire a site in The Bronx at a cost of not more than $200,000, and to construct hospital buildings which may cost $300,000 more, "for the purpose of providing suitable accommodation for a reception hospital for persons injured or taken ill suddenly in the Borough of the Bronx and for cases of infectious or contagious diseases." Another amendment places the control of the hospital in the hands of the Board of Trustees of Bellevue and Allied Hospitals.

New State Charities Bill.—The bill carrying into operation the recommendations of Gov. Odell for a change in the system of management of State reformatory, charitable, and eleemosynary institutions has been drawn by the special committee appointed at the conference of legislators held in the Executive Chamber two weeks ago, and has been sent to New York City for consideration by the State Board of Charities at its meeting, to be held in that city. The measure is different in many respects from the bills which heretofore have been outlined by those who have been following this proposed legislation. It does not abolish the State Board of Charities nor the boards of managers of the institutions. The power of these bodies, however, are modified, and the control and management of the institutions are practically reposed in a central bureau to be located in this city. The prominent features of the measure are:

First.—The Governor of the State shall appoint a Superintendent, under whose direct supervision the institutions will be managed, and who will receive a salary of $4,000 per year, with $1,500 for expenses.

Second.—The Superintendent is empowered to appoint a superintendent and steward of each institution and to exercise a general supervision over them.

Third.—The Superintendent of each institution is vested with power to appoint the subordinates of the institutions and is held responsible for the manner in which the institution is conducted.

Fourth.—The steward is made the purchasing agent of the institution he is connected with, subject to regulations to be prescribed by the State Board of Charities.

Fifth.—A State Improvement Commission composed of the State Controller and the President of the State Board of Charities is created. This commission is to have the power to ratify or reject plans for new buildings and for improvements to institutions, and no new buildings or improvements can be recommended to the Legislature for appropriations without the consent of the State commission.

Sixth.—The power of estimate for supplies is taken from the State Controller and reposed in the Superintendent of Institutions. He is charged to inaugurate a system of purchases in bulk, such as now is in operation in the State hospitals for the insane.

Seventh.—Local Boards of Managers retain the power of visitation and inspection of the institutions which they have heretofore managed. They are to be subject to the control of the State Board of Charities, and may be called upon at any time to investigate complaints and to make reports on the condition and needs of the institution.

Eighth.—The State Board of Charities retains the power of visitation and inspection which it now exercises, under the Constitution and the State Charities law, but the power of passing on plans for the improvements to and betterment of the institutions is taken from it and reposed in the State Improvement Commission, composed of the Governor, the Controller, and the President of the State Board of Charities.

Ninth.—While the power of passing upon estimates for supplies is taken from the State Controller, he still retains the power of auditing all bills for the expenditure of public moneys in behalf of the institutions. It is like the State Lunacy Bill, most obnoxious in its main features, and it can only be regretted that the Governor should be so set on the passage of such measures as to jeopardize seriously his reputation for integrity.

Charities Bill Not Approved.—The State Board of Charities held a special meeting at the United Charities Building last week and discussed the new Charities bill drafted by Gov. Odell. There was considerable opposition to some of the important details of the bill. The portion giving the general superintendent power to appoint officers of the institutions was freely criticized, and it is understood that the bill must be materially changed before the board will give its approval. The final decision of the board was embodied in a set of resolutions which will be sent to the Governor on Monday. The board refused to make the resolutions public until after the Governor has seen them.

Protection Against Public Nuisances.—At the request of the Health Board the Police Department has detailed a force of plain-clothes men to travel on all surface lines, elevated roads, and ferries, on the lookout for persons who expectorate on the floor. By an arrangement with the City Magistrates all persons arrested are to be fined. Commissioner Lederle is determined to put a stop to the nuisance. The management of the Metropolitan Street Railroad informed Dr. Lederle that they would welcome all complaints against conductors who do not act on the suggestion of passengers, and caution offenders.

Protest Against Pure Food Bills.—The drug trade section of the New York Board of Trade and Transportation have forwarded a protest to the Senators at Albany against the Senate Bills Nos. 336 and 497, now pending, and known as the "Pure Food" Bills. The protest advocates the reference of the subject of pure food to a commission or to chemists identified with the department of the State. It is declared that to define adulterations requires the investigation of scientific men, and that hasty legislation would work injustice to consumer and producer alike. The comprehensive provisions of Senate Bill No. 336 would, in the judgment of the members of the drug trade section, open the way for endless litigation as a result of disagreements as to what constituted "harmful substances," and the discrimination against the two well-known preservative agents which are named in the bill is in itself without justification in the clinical experience with those chemicals, it is declared. Bill No. 497 is said to lack definiteness in its provisions as to what is injurious to health, and its enforcement would be based on opinions concerning which there is disagreement. The protest states that such legislation as the two bills represent is at variance with the laws of many other States, between which and New York State there is a liberal exchange of products. The protest is signed by John M. Peters, chairman of the committee on legislation; Jesse L. Hopkins, chairman of the drug trade section, and William F. McConnell.

New Ophthalmic Institute.—The New York Ophthalmic and Aural Institute, which now occupies the buildings 44 and 46 East Twelfth Street, will in the near future erect a handsome structure at the northwest corner of Central Park West and Sixty-fourth Street. Dr. Herman Knapp, who is the executive head of the institute, declined to say anything yesterday regarding plans for the improvement of the new site, and those members of the Trustees who could be reached, including Charles T. Barney, said that the plans were as yet in somewhat indefinite shape. The price paid for the plot has not been made public, but it may be assumed that it shows a substantial advance over $174,000, the figure at which the Century Realty Company acquired the property from the various owners a few months ago. The New York Ophthalmic and Aural Institute was organized in 1869. In connection with it there is maintained the School of Ophthalmology and Otology for the training of advanced medical students as eye and ear specialists. The institute's present quarters on Twelfth Street have long been inadequate, despite the fact that something over a year ago an adjoining house was deeded to it as a gift by Dr. Knapp and connected to the other buildings. Dr. Knapp will celebrate on March 17th his seventieth birthday, and in 1904 his fiftieth anniversary as a medical practitioner. He was professor of ophthalmology at Heidelberg from 1864 to 1868. Since 1868 he has practised his profession in this city.

Academy of Medicine.—The next regular meeting of the Section on Otology will be held Thursday, March 13th. Dr. Clarence John Blake of Boston will read a paper on "Tension Anomalies in the Sound Transmitting Apparatus of the Middle Ear."

The Section on Pediatrics will also meet Thursday, March 13th. Dr. T. Halsted Myers will read a paper on "Acute Joint Diseases of Infancy;" Dr. Henry Ling Taylor will present one on "Chronic Joint Diseases in Children."

The following have been recommended to resident fellowship: Drs. Charles Herman, John Leshure, Ernest Ellsworth Smith, Albert E. Sumner and James D. Voorhees. Dr. Willis Noble of Montclair was admitted to non-resident fellowship.

The following are some of the recent accessions to the Library: Allingham, W., & Allingham, H. W.,

Diseases of the Rectum; American Year-book of Medicine and Surgery, under the general editorial charge of G. M. Gould; Ball, J. B., Diseases of the Nose and Pharynx; Bruce, A., Ideal Health and How to Attain It; Crile, G. W., Problems Relating to Surgical Operations; Gerber, P. H., Atlas der Krankheiten der Nase; Hadley, W. J., Nursing: General, Medical and Surgical; Hanot, V., La Cirrhose hypertrophique avec Ictère chronique; Herter, C. A., Chemical Pathology; Horrocks, W. H., Bacteriological Examination of Water; Kocher, T., Hirnerschütterung, Hirndruck und chirurgische Eingriffe bei Hirnkrankheiten; Marshall, J. S., Operative Dentistry; Mercier, C. A., Psychology: Normal and Morbid; Munk, I., Physiologie; Reports of the Society for the Study of Disease in Children, Vol. I.; Roger, G. H., Les Maladies infectieuses; Schultze, F., Die Krankheiten der Hirnhäute und die Hydrocephalie; Simon, C. E., Clinical Diagnosis; Theobald, F. V., Culicidæ or Mosquitoes; mainly compiled from the collections received at the British Museum; Traité de Médecine, 2. éd. publiée sous la direction de MM. Bouchard et Brissaud; Transactions of the American Orthopedic Association; Transactions of the Colorado State Medical Society; Transactions of the Epidemiological Society of London; Transactions of the Ohio State Medical Society; Transactions of the Society of Anæsthetists, London; Weygandt, W., Psychiatrie; Wheeler, M., The Baby: His Care and Training; Whitla, W., Dictionary of Treatment; Williamson, R. T., Paralysis Agitans.

PHILADELPHIA.

To Appeal from Verdict of Court.—The Philadelphia County Medical Society at the meeting of February 26th appropriated the sum of $200 to aid in appealing the case of Dr. Righter, against whom a jury recently returned a verdict of $1,000 for alleged negligence in vaccination. Much indignation was manifested by members of the Society against the injustice of the verdict and individual members volunteered to subscribe enough to carry the case to the last resort if need be.

Symposium on Cholecystitis.—The meeting of the County Medical Society, February 26th, was devoted to a consideration of cholecystitis. Dr. Joseph McFarland spoke on the pathology, Dr. Joseph Sailer on the etiology and diagnosis, Dr. J. Chalmers Da Costa on the surgical diagnosis and treatment, and Dr. S. Solis Cohen on the medical treatment. Dr. Da Costa, in speaking of the cause of cholecystitis, stated that infecting organisms generally died before producing any effect on the gall-bladder when bile was running. Therefore infection and stagnation influence each other greatly as causative factors. The subjects of movable kidney and appendicitis were thoroughly considered under the question of diagnosis and the surgical treatment fully discussed, the policy of aggression being endorsed. Dr. Cohen stated that there was no specific treatment for cholecystitis, the general rule to be laid down being the securing of cleanliness, external and internal. This is brought about by diet, stimulants, hydrotherapy, etc. Sodium succinate in five-grain doses, four or five times daily, has given good results in some cases. In discussing the subject, Dr. J. C. Wilson said that cholecystitis presented one of three common conditions—catarrhal or purulent inflammation or contraction of the gall-bladder, with or without adhesions to the neighboring tissues. A point emphasized was that cholecystitis is rather frequent in the latter stages of typhoid fever. In a considerable proportion of such cases relapses occur, hence he has come to rather expect a relapse when cholecystitis develops. Dr. Wilson believes that surgical interference is advisable when from repeated attacks of colic, the presence of a tumor, etc., the diagnosis is reasonably sure. This is true whether the disease be accompanied by jaundice or not or whether gall-stones be present or absent. Early operation is comparatively easy and the danger of severe hemorrhage is much less.

Dr. Dawbarn Visits Philadelphia.—Dr. Robert H. M. Dawbarn of New York, whose essay recently won the Gross Prize in Surgery, visited this city during the past week. On the evening of February 25th, he addressed the students of Jefferson Medical College and later attended the annual banquet of the W. W. Keen Surgical Society. The following day he operated in Dr. Hearn's clinic at the Jefferson Hospital. Dr. Dawbarn spoke very briefly on the subject of excision of the carotids, giving a few of the details necessary for success in that method of treating certain malignant growths. Dr. Dawbarn is now making experimental injections into the internal maxillary and other small arteries, in conjunction with excision of the carotids, to prevent a return of the circulation.

Obituary.—Dr. Francis W. Lewis died March 2 of pneumonia, aged seventy-seven years. Dr. Lewis graduated from Jefferson College in 1846, served in a military hospital during the Civil War and was prominently connected with the Children's Hospital from the time it was founded.

New Dispensary to Be Opened.—An office under the management of Drs. Alice Norton, Gertrude Walker, and Kate Baldwin is to be opened in this city in the near future for the purpose of aiding a class of patients who cannot afford to pay the fees of regular physicians, but do not care to visit hospital clinics. The office is to be open during the evening and medical treatment will be given at very moderate prices. The project is supported by many physicians and also by the Pennsylvania Association of Women Workers.

Ferment-Chemistry of the Blood.—At the meeting of the Pathological Society February 27th Dr. Alfred C. Croftan spoke on "The Ferment-Chemistry of the Blood, with Particular Reference to General Metabolism." Dr. Croftan prefaced his remarks by stating that every physician must have asked himself why substances taken as food are oxidized in the body at its low temperature and not in the air. This is proven by the elimination of more oxygen than is inspired and is brought about by the various complex processes of the body included under the term metabolism. Metabolism is a process including two stages. The first stage is anaerobic and is carried on in the center of the cell by ferments secreted, not excreted, by the cell itself. The second stage is oxidative and is carried on at the periphery of the cell by ferments carried in the blood. An example of the action of these ferments is seen in the changing of albumose and peptones (formed from food) into serum albumin as soon as they have passed through the intestine in the soluble form into which they had been converted in the alimentary canal. By these ferments many complex substances, such as urea, may be formed without the presence of oxygen. Blood ferments are difficult of separation, being obtained only in extracts. Croftan believes that these ferments are carried by the leucocytes. An exceedingly interesting point was then discussed by Dr. Croftan, namely, the question of incubation. Experiments to determine this point are now under way by Dr. Croftan and although they are yet incomplete enough has been learned to justify a hypothetical explanation. Experiments show that there are enzymes formed in the body so akin to protoplasm as almost to seem alive. A certain amount of pepsin, for instance, will digest a certain amount of albumin. If now the pepsin is diluted and treated in a certain manner it will digest proportionately more al-

bumin than it did before. In this way it may be diluted many times, the results leading to the conclusion that pepsin is capable of regeneration and of assimilation. This leads to the hypothesis that minute amounts of toxin introduced into the body may increase during the incubation period. This is approaching closely the question of life itself. Further results will be awaited with interest.

Conditions for Psychiatric Research.—Dr. Adolf Meyer, Director of the Pathological Institute of the New York State Hospitals, by invitation delivered an address on the above subject at the February meeting of the Philadelphia Neurological Society. Dr. Meyer outlined in part the principles upon which he believes the Institute should be conducted for the benefit of psychiatry. He stated that only thirty to sixty per cent. of the cases conform to the text-book description of the disease in question. Exact records of cases are more necessary in this than in other fields. Most hospitals have an abundance of pathological anatomy reports, but are without a stock of reliable observations. No striking progress in psychiatry has been made except that obtained from well-observed patients. Physicians should be exceedingly careful to make a somatic and psychiatric correlation in the study of all mental cases. The proper place for such study is the hospital for mental diseases. To be true, all pathological material should be carefully worked up, but the psychiatrist should rely mainly on observations, aiming to replace the impressionist method by recorded cases. This means not only the so-called "interesting" cases, but all cases, features promising to be very helpful in future cases being especially elaborated. Examinations of the blood, urine, etc., have not produced any startling discoveries. These points have been arrived at by Dr. Meyer's experience before coming to his present position and they are to guide his reorganization of the Institute. The wards of hospitals must answer for a clinical institute until a special psychopathic hospital is erected. A clinical nucleus must be formed by studying the constitution of the blood, blood pressure, excreta, etc. Some of the departments in the institute will be the psychological, chemical, histological, toxicological, etc. In this way will be combined a knowledge of practical work with a knowledge of psychiatry, both of which are necessary for men working in hospitals for the insane. In this way also help in mastering the subject far beyond that given in medical schools will be made possible. Each hospital in the State can decide on its own policy and choose from the Institute the men best adapted to carry out that policy. A tangible evidence of the policy outlined will be a wider knowledge of insanity, its prevention, and cure. The State must do its part since it, as well as the medical schools, has not yet furnished sufficient opportunities for psychiatric research. The greater part of the material is monopolized by a few favored institutions. The State must aid the hospitals.

CHICAGO.

To Establish a Hospital.—At a meeting of the Alumnæ of the Woman's Medical School of the Northwestern University, held at the Sherman House, February 27th, it was decided to establish a hospital to perpetuate the memory of the school that has been sold by the Northwestern University. The new hospital will be entirely under the management of women physicians. All the different branches of medicine, including surgery, will be practised. Alumnæ of the school which has been sold will act as its physicians. No man can enter this hospital except as guest, janitor or patient. There will be an advisory board composed of women, also. This board will be formed largely of the Alumnæ, probably, who live outside of Chicago. A committee was appointed to carry forward the plans for the hospital, so that they will be in definite shape by the time the Alumnæ gather here in June. The hospital will afford a training-school for young women who desire to become professional nurses. The expenses during the first year will be light, probably not more than four thousand or five thousand dollars being laid out, it is said, in securing a building and equipment. The institution will probably be opened next fall. Eventually, it is planned to build a large hospital, probably rivaling any institution in Chicago. Among those who are taking an active part in the planning of the new hospital are Dr. Sarah Hackett Stevenson, Dr. Eliza H. Root, Dr. Effa V. Davis, and Dr. Mary J. Kearsley. About thirty members of the Alumnæ were present at the meeting.

Endows Consumptive's Home.—Charles L. Adams of Chicago has given $30,000 for the purpose of building a home in Denver, Colorado, for needy consumptives. The gift is in memory of his wife, whose name it will bear. Mr. Adams also offers $20,000 toward endowing and maintaining the plant, providing Rev. F. W. Oakes, who originated the plan, raises the endowment to $50,000.

Promotion of Dr. Bouffleur.—Dr. A. I. Bouffleur, of this city, who has been identified prominently with the medical and surgical department of the Chicago, Milwaukee and St. Paul Railroad, has been promoted to the position of chief surgeon, Dr. Solon Marks, the former chief surgeon of the road, having resigned.

For Better Clinical Work.—Efficiency of the County Hospital is to be increased by additions to the laboratory and pathological museum. An X-ray machine was installed two weeks ago, an official skiagrapher was appointed Monday, February 24th, and instruments have been received from Springfield incorporating the Cook County Clinical School. The incorporators were Warden Healy, President Hanberg, and Superintendent McLaren, and they and their successors in office will continue to direct and manage the school.

The Laboratory.—The nucleus of the laboratory was obtained last year through the contributions of County Commissioners, who turned over part of their salaries to the County because on the platform on which they had been elected they stood for a maximum salary of $3,000, the budget reduced the salary of $4,000 to $3,600 for each Commissioner, and the balance was donated. Since then contributions have been received from several sources, and the laboratory has grown beyond the control of the County Board. In order to provide suitable conditions for rapid growth, the County officials decided to incorporate the laboratory and museum into a school, the management of which is placed in the hands of the Warden, the President of the County Board and the Superintendent of Public Service.

Appointment of Dr. Neely.—Dr. John R. Neely has been appointed Medical Director of the County Institutions at Dunning by President Hanberg of the County Board. The selection was made upon the recommendation of Drs. Frank Billings and Hugh T. Patrick, of the subcommittee of the Advisory Commission, recently named by President Hanberg, to consider ways and means of improving the County Institutions. There will undoubtedly be a complete reorganization of the medical staff, also of the force of attendants and nurses. Dr. Neely was appointed because of his ripe experience and training, which, in addition to his recognized standing in the profession, will make him more valuable to the institutions at this time. To accept the medical directorship of Dunning, Dr. Neely will resign his connection with the City Health Department. He stands

high in the profession and takes with him to Dunning the endorsement of Chicago physicians.

Decision of the Supreme Court Regarding Healers.—The Supreme Court of Illinois has decided that magnetic healers and osteopaths must have a license to practise, in the case of the People *versus* George P. Gordon, an advertising healer of Rockford. It is said that Gordon was charged with practising medicine without a license, and, that after trial the Circuit Court directed the jury to find for the defendant. The Supreme Court reversed and remanded the case. The following is the text of the finding of the Court: "We all agree that the object of this (the statute) is to protect the sick and suffering and the community at large against the ignorant and unlearned, who hold themselves possessed of peculiar skill in the treatment of disease, and to prevent them from holding themselves out to the world as physicians and surgeons without having acquired any knowledge whatever of the human system or of the disease and ailments to which it is subject. Without some knowledge of the location and offices of the various nerves, muscles, and joints, the manipulation of those parts and the flexing of the limbs cannot be intelligently, if, indeed, safely, practised. Merely giving massage treatment or bathing a patient is different from advertising one's business or calling to be that of a doctor or physician, and, as such, to administer osteopathic treatment. The one probably falls within the profession of a trained nurse, while the other does not."

Resignation of Dr. Hammond.—It is said that Warden Healy of the Cook County Hospital has demanded the resignation of Dr. Herbert R. Hammond, a member of the attending staff, because he allowed an interne to perform an amputation under his personal supervision. This action the Warden construed as a violation of the rule prohibiting internes from performing operations in which an anesthetic is administered.

Scarlet Fever.—In contrasting the mortality from scarlet fever and smallpox during the past three years, the Department of Health shows that the mortality from the first was 924, while smallpox claimed only 7 deaths. The hope is expressed that in the foundation of the McCormick Memorial institution for infectious diseases, in which this infection is the first to be studied, that a disease, often more merciful in the life it takes than in the crippled survivor it spares, may finally be shorn of its terrors.

The West Side Hospital.—This hospital has just installed a model operating-room on its fifth floor for the especial use of its attending staff and the professors in the Chicago Clinical School. The room is excellently lighted by three side windows and a circular, fifteen-foot skylight provided with a revolving, adjustable screen, which secures the maximum north light. No hospital in Chicago is better equipped to furnish efficient service than is the West Side Hospital, and the following list of attending physicians and surgeons guarantees skill and experience of the highest grade: Surgeons, Drs. D. A. K. Steele, John B. Murphy, Thomas A. Davis, Charles Davison, E. H. Lee, and Alexander C. Wiener. Gynecologists, Drs. Henry P. Newman, George W. Newton, F. S. Hartman, and S. G. West. Oculist and Aurist, Dr. William L. Noble. Internal Medicine, Drs. Ralph Michel, and P. H. Conly.

CANADA.

Quebec College of Physicians and Surgeons.—The following physicians were recently elected to represent the different universities of the Province of Quebec on the College of Physicians and Surgeons of the Province: University of McGill, Drs. Craik and Lafleur; Laval University, Quebec, Drs. Simard and Catellier; Laval University, Montreal, Drs. E. P. Lachapelle and Demers; University of Bishop's College, Montreal, Drs. F. W. Campbell and J. H. McConnell.

Obituary.—The death is announced of Dr. David Roberge, at the age of thirty-two years, a prominent young French-Canadian practitioner of Montreal. Dr. Roberge was graduated from Laval University and for some time after graduation served as a house surgeon in the Notre Dame Hospital, Montreal. Death was caused by bronchopneumonia.

Dr. John Coventry, Medical Health Officer, Windsor, Ont., died on February 22d from pneumonia. He was a past president of the Ontario Medical Association.

The Medico-Chirurgical Society of Montreal.—This Society meets on the first and third Fridays of the month from October to June inclusive. It has recently acquired fine, new, commodious quarters in the West End Branch of the Bank of Montreal. There is a large assembly hall, comfortably furnished and capable of seating 125 persons. In addition there is a coat-room, a reading-room, a stock-room for the library, and a committee room. All is in charge of an attendant. The reading-room is supplied with the best medical journals and is open from 2 to 6 p.m. and from 8 to 11 p.m. It is proposed to admit non-resident practitioners to membership at a nominal fee.

Undergraduates' Medical Society of McGill University.—The new reading-room of this college society has been completed. It is supplied with the leading medical and scientific journals and the daily papers. The Society was organized in 1879 by Drs. Osler and Buller, and in 1886, in order that it would be properly supported financially, the Medical Faculty adopted the plan of charging each medical student $1.00 per annum along with his other fees. Since that time the finances of the Society have been in a very satisfactory condition. The classes of '01, '02, '03 and '04 have recently erected in a conspicuous place in the reading-room a tablet to the memories of two former students, Harold L. Borden, B.A., and A. Patrick O'Reilly, of Canning, N. S., and Hamilton, Ont., respectively, who lost their lives on the battlefields of South Africa in 1900.

Disease Among Immigrants.—Statements have recently been going through the public press, copied from the United States Bureau of Immigration report, to the effect that diseased immigrants gain an entry into that country through Canadian points. A discussion took place in the House of Commons at Ottawa the other day on a motion to increase the estimates in order to protect the Dominion from the introduction of smallpox by maintaining a constant and close quarantine at Sarnia, Windsor and Niagara. The Minister of Agriculture, under whose care quarantine is, took occasion to state that the diseases referred to were not such as could be quarantined and from what he knew of the matter he was satisfied that these reports in the press were entirely unfounded. He considered that the quarantine laws were more rigidly enforced in Canada than in the United States.

Dominion Registration.—The bill to provide for a Dominion Medical Council has been again introduced into the Canadian House of Commons by Dr. Thomas G. Roddick, M.P. There is very little change from that introduced last session, the change being with regard to the representation on the proposed Council which will now be on the basis of the medical population of each Province. Dr. Roddick has asked that when the measure has received its second reading it be referred to a special committee composed of members of Parliament who are physicians and two or three leading lawyers. When the Bill is before this special committee delegations of medical practitioners from every Prov-

ince of the Dominion will go to Ottawa, and a strong effort will be put forth to have the Bill passed by both Houses of Parliament.

Bill to Amend the Ontario Medical Act.—The Senate of Toronto University and the Medical Faculty thereof are not going to allow the proposed amendment to the Ontario Medical Act to pass without a determined effort to save the college representation. The Bill provides for the extinction of the College and Homeopathic representation on the Medical Council. A lengthy memorandum has been prepared on behalf of the Medical Faculty of the University and has been presented to the Government. In substance it is as follows: (1) It excludes from the body entrusted with fixing and determining the standard of medical education and prescribing the curriculum of studies those who, by reason of their avocation, as well as training and experience, are, if not best fitted, at least specially qualified for performing these duties. (2) It hands over to a practically irresponsible body the entire and absolute control of medical education and creates a close corporation or guild. (3) It imposes on the universities and colleges engaged in the work of medical education the obligation of following the curriculum of studies prescribed by the Council without having any voice in the framing of it. (4) It violates the compact entered into with the universities and teaching bodies by which they were given representation on the Council in consideration of their giving up the right to confer degrees or diplomas in medicine and surgery, entitling the possessor of them, without further examination, to practise upon obtaining his license or becoming registered.

Canadian Surgeons and the Medical (Extensions) Act of the English Parliament.—The Bill to amend the Medical Act of 1858 has been reintroduced into the British House of Commons by General Laurie, a member thereof, who was some years ago a member of the Canadian House of Commons from Nova Scotia. It has been suggested to General Laurie by the fact that the War Office has refused to allow colonially trained surgeons from Canada to attend professionally on other than Canadian troops on active service in South Africa, holding that it was contrary to the Medical Act of 1858. Leading surgeons of Canada, at the opening of the war, volunteered for service, but had to be refused and on this account General Laurie seeks to remove these disabilities. *The Lancet* does not consider that the chances of the amendment being discussed during the present session of the English Commons are very bright.

GENERAL.

Hospital Wing in Memory of Cornelius Vanderbilt.—Mrs. Cornelius Vanderbilt is about to have erected a wing to the Newport Hospital in memory of her late husband.

League Against Infant Mortality.—A society bearing this name has been formed in Paris for the purpose of combating in every possible way the excessive and avoidable mortality of early infancy. The following officers have been appointed: Messrs. T. Roussel, President; Paul Straus and P. Budin, Vice-Presidents; Josias and Variot, Secretaries; Henri de Rothschild, Treasurer.

Shelby County Medical Society.—A temporary organization of Shelby County (Tenn.) Medical Society was effected February 13th and was made permanent February 17th. The following officers were elected for the first year: J. H. Stolper, M.D., Ph.G., President; B. L. Branch, M.D., Vice-President; Geo. E. Pettey, M.D., Secretary; J. H. Liebkemann, M.D., Treasurer; John H. McKay, M.D., Reporter. This is the County in which the city of Memphis is situated; it contains about 400 physicians.

Hospital for Americans in Paris.—A splendid gift has been made for the benefit of the American colony in, and, of American visitors to, Paris by Edward Tuck, who has for many years resided in that city. Mr. Tuck has decided to defray the entire expense of establishing the free American hospital in Paris, announcement of which has already been made, and the ground for which has already been bought in the Passy Quarter. The hospital is to be named Franklin Hospital, and, besides being built on the latest American model, it will be managed entirely by American physicians and nurses. That the proposed hospital will fill a deeply-felt want is shown by the fact that the services of several American nurses who came recently have been in constant demand. Franklin Hospital will be situated in one of the most healthy parts of Paris. It will be surrounded by extensive grounds. Dr. Magnin, a well-known American physician in Paris, will be the director of the institution. Building will be begun in a few weeks, and it is expected that the hospital will be opened in 1904.

Treatise on Smallpox.—A very timely treatise on smallpox is announced for publication early in April by J. B. Lippincott Company. It is written by Dr. George Henry Fox, Professor of Dermatology in the College of Physicians and Surgeons, New York City, with the collaboration of Drs. S. Dana Hubbard, Sigmund Pollitzer, and John H. Huddleston, all of whom are officials of the Health Department of New York City and have had unusual opportunities for the study and treatment of this disease during the present epidemic. The work is to be in atlas form, similar to Fox's "Photographic Atlas of Skin Diseases" published by the same house. A strong feature of the work will be its illustrations, reproduced from recent photographs, the major portion of which will be so colored as to give a very faithful representation of typical cases of variola in the successive stages of the disease, also unusual phases of variola, vaccinia, varicella, and diseases with which smallpox is liable to be confounded. These illustrations number thirty-seven and will be grouped into ten colored plates, 9½ x 10¼ inches, and six black and white photographic plates. The names of Dr. Fox and his associates assure the excellence of the work, in which will be described the symptoms, course of the disease, characteristic points of diagnosis, and most approved methods of treatment.

Medical Society of Tennessee.—The Memphis meeting of the Society is only four weeks distant. Time begins to press. The preliminary program will be issued early in March and the Secretary is particularly desirous that it should be as full and attractive as possible. To this end all members are earnestly requested to contribute a paper and to send in title. The Committee of Arrangements is actively at work in the interest of the meeting and all who come are assured of a warm welcome from the Memphis profession. The Secretary calls attention to the fact that this will be the most important meeting the Society has held for many years. Constitutional amendments involving radical departures from the established policy will come up for final action, and every member should feel a personal responsibility in connection with the consideration and disposal of them. (See Transactions, 1901, pp. 22 and 25.) Attention is also again directed to the Prize Essay Contest, the conditions of which are fully set forth on pages 39 and 40 of the Transactions.

Country Life in America.—The March Country Life in America heralds the coming of spring, and, with added pages, offers a profusion of superb pictures relating to all sorts of wild and domestic life of the

woods, of the fields and of country places. This really magnificent periodical has made in the few months of its existence a lasting name for beauty and interest. As a recommendation by the doctor to his patient it is unsurpassed.

Validity of the Ionization Theory.—In a long review in *Nature* for January 30th, W. R. C. discusses the validity of the theory of ions now on its trial. A few paragraphs may be quoted here. It follows from the arguments adduced that there is no such connection between freezing-points and boiling-points of solutions as the theory demands. Often there is not even a qualitative agreement, let alone a quantitative one. In the realm of physiology the theory does not represent the facts. The heats of neutralization of acids and bases have been used as an argument in favor of ionization, but recent experiments have shown the theory to be not only inadequate, but unnecessary. Neither can the theory be brought into harmony with the law of mass-action; and this is one of the very strongest arguments against it. The ionization theory is at its best in explaining electrolysis, but even here, there are many phenomena that are left unexplained. For example, why are the deposits of silver from some solutions poorly adherent and from others dense and well adhering, the potential—difference and current—density being the same? The analogy between gases and solutions has clearly been pressed too far, and the fact that we are only reasoning by analogy has been forgotten. The solution of a substance and the expansion of a gas are really very different. A gas will expand *in vacua* or mix with any other gas, but a substance will not dissolve in every liquid. Here lies the chief difficulty of the theory. It neglects the all-important rôle of the solvent. It fails to emphasize the fact that solution takes place because of a mutual attraction between solute and solvent, and that this attraction is the essence of osmotic pressure, which is close related to, if not absolutely identical with, chemical affinity.

Distribution of Firm's Stock.—The firm of Parke, Davis & Co., manufacturing pharmacists of Detroit, has adopted the policy of other large corporations of encouraging its employees to become shareholders. This company proposes to issue 4,000 shares of its capital stock, and permit the oldest among its employees, especially those in important positions, as managers, superintendents and foreman, to purchase this new stock at $55 a share. The present market value of the stock is $70 a share, and face value, $25 a share. The company announces that it is not taking this action for philanthropic reasons, but because it considers it good business judgment to have its men in important positions interested in the profits of the business.

Tua-Tua for Leprosy.—Medical men are interested in the newspaper reports from Honolulu and Tahiti of successful results obtained in the treatment of leprosy from the active principle of the tua-tua shrub. The tua-tua's scientific name is *Jatrapha gossypifolia*, and it comes from Venezuela. Nearly three years ago the Department of Agriculture sent twenty-seven of the tua-tua plants to Dr. Carmichael, United States Marine-Hospital surgeon, then at Honolulu, but now in San Francisco. The plants were set out in the experiment station grounds in Honolulu, where they flourished, waxed green and produced many buds. With the plants came statements from Venezuela that leprosy had been successfully treated with the extract. The shrub is called in Venezuela *frailejan purgo*, on account of its purging qualities. Dr. C. E. Camp, assistant in the bacteriological laboratory of the Board of Health of Hawaii, has been experimenting on lepers in Honolulu ever since the receipt of the shrub. The direct effect of the medicine is to reduce the frightful swellings which disfigure the features of the lepers, and which distort their extremities. In Tahiti really wonderful advance toward the cure of leprosy has been achieved by the use of the shrub, but in Hawaii it has been difficult to induce the lepers to undergo the treatment. The use of the medicine is generally accompanied by severe colics, and the Kanakas will not submit to the pain, even though a promise is held out of a partial cure of their terrible affliction. The fact is that leprosy among the Hawaiians is not looked upon with the horror that it possesses for Americans and Europeans, and save for the isolation on Molokai, which leprosy entails upon its victims, the latter show little disposition to do anything to ameliorate their physical condition. The lepers are free to accept or refuse treatment, and cannot be forced to take the medicine. A Portuguese in Honolulu, who had leprosy, was given the tua-tua, and, according to Dr. Camp, shows absolutely no symptoms of the disease now.

Care of the Insane in Washington.—A deficiency appropriation of $35,000 is asked in a communication recently transmitted to the House by Secretary Shaw from Secretary Hitchcock for the support of the Government Hospital for the Insane for the present fiscal year. A statement by Dr. Richardson, superintendent of the hospital, which accompanies the request, states that the daily average attendance for the current year will exceed that of the year previous by about 134. The advanced price of many articles of food is also given as a reason why more money is needed. The fresh meat contract alone is increased $5,000 over last year. In addition to this it has been necessary to purchase 200 bedsteads, with the necessary bedding.

Obituary.—Dr. Elizabeth B. Wakeley died on Thursday at the residence of her son, Dr. William A. Wakeley, 420 South Main Street, Orange, N. J., where she was visiting. She had been a practising physician in New York State for more than thirty years. She was born in Connecticut seventy years ago, but had spent most of her life at Levanna, on Cayuga Lake, N. Y.

Dr. Edward Mott Moore, a prominent citizen of Rochester, N. Y., died March 3d at the age of eighty-eight years. He was born in Rahway, N. J., on July 15, 1814, of Quaker and Huguenot ancestry. After attending school at Flushing, Long Island, he was sent to the Rensselaer Institute at Troy and afterward came to Rochester, in 1828. He was graduated from the University of Pennsylvania in 1838, and from the Medical College at Woodstock, Vt., in 1854. He was known prominently in the work of the Red Cross Society of New York State, and as "The Father of the Parks" of Rochester.

Dr. Worthy Streator, a physician of Cleveland, died March 3d. He was the man after whom the city of Streator, Ill., was named. In early life Dr. Streator helped to build what is now a portion of the Erie Railroad. He was eighty-five years old.

Dr. Arthur T. Muzzy, of No. 100 East Fifty-seventh Street, New York, well-known as a specialist in diseases of the eye, ear and throat, died early Tuesday morning in the Presbyterian Hospital from heart disease. He was the son of the late Rev. Dr. Clarendon Vey Muzzy, a missionary to India, and was born fifty-one years ago in Madura, India. Dr. Muzzy has always been very active in the hospital work of New York and was especially devoted to the interests of the Charity Alumni Association.

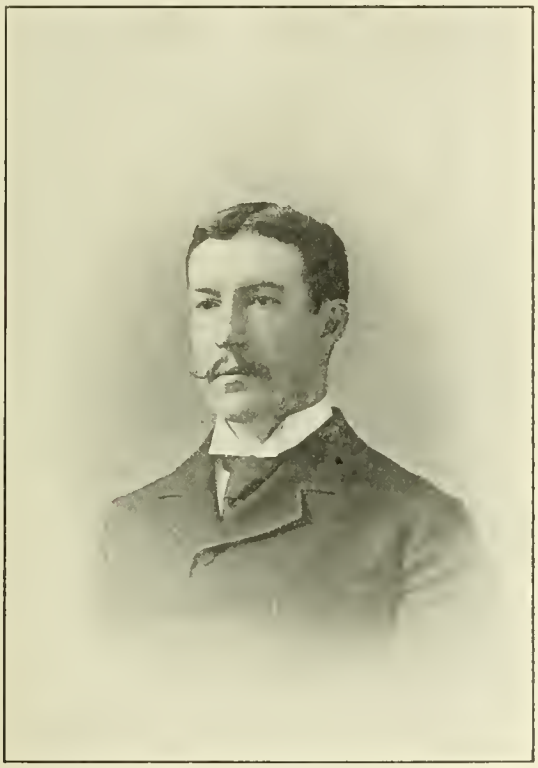
OBITUARY.

ERVIN ALDEN TUCKER, M.D.

The sudden death of Dr. Ervin Alden Tucker, from pneumonia, on March 3, removes from the profession one of the most able of the younger men of New York City. Although Dr. Tucker was but forty years of age, and had been in private practice as an obstetrician for only seven years, yet he was entering the first ranks in his specialty, and had become well-known as a consultant physician in New York and other cities.

His almost phenomenal success, and the rapid growth of his fame, were, however, the result of years of preparation, when with concentrated energy and singleness of purpose he devoted every faculty to his one interest and ambition.

Dr. Tucker was born Feb. 2, 1862, in Attleboro, Mass., where his early education was obtained. He



ERVIN ALDEN TUCKER, A.M., M.D.

was prepared for college in Moury and Goff's Classical School in Providence, R. I. At Amherst College, where he took the degree of B.S. in 1885 and M.A. in 1888, he laid the foundation for his scientific work, instead of pursuing his classical studies. An interval of two years passed before he began his medical studies, during which time he taught modern languages in Betts Academy in Stamford, Conn.

During the three years of his medical course at the College of Physicians and Surgeons, he was a marked man, and his unusual faculties and apparent inclination for the branch he chose, were noted by his professors. When he graduated in 1889, it was as one of the ten honor men, and a winner of the second Harsen prize. It is remembered, that when he received his honors, some one asked why young Tucker won such a prolonged round of cheers from his class-mates, and the reply of one of his fellow students was to the effect that his class had hoped that he would be a prize man because he had gone through the college on his own efforts.

After a six months' residence in the nursery and childs' hospital he went to Germany where he devoted all his time to the study of obstetrics under Olshausen, Winter, Dührssen and Winckel. He studied various methods of conducting lying-in hospitals, and came home ready for his chosen work.

In the Spring of 1890 his career really began, for he was then appointed resident physician in the Sloane Maternity Hospital. During the five years that he worked there he had the satisfaction of seeing the service increase from 400 to 900 confinements a year, and of seeing the Hospital grow, by reason of his interest and methods into the largest obstetrical hospital as well as the most fully equipped in the country.

Before Dr. Tucker left the Sloane Maternity Hospital he married Miss George Anna Crispell of Rondout, N. Y., and together, each with the interest of the hospital at heart, they helped the founder of that institution to carry it to the state of perfection.

When in 1895 he resigned to begin private practice in obstetrics, he was made Assistant Attendant to Sloane, and was shortly after appointed as one of the attendants to the Obstetric Division of the City Hospital on Blackwell's Island.

Dr. Tucker's practice increased with a rapidity that was startling. But there was hardly a young physician in the city who did not turn to him, considering him one of them, and yet as able as the most celebrated of the older men to help him in difficult cases.

He was a master of technic, and he had that swift sure judgment that comes with long experience and well thought out methods. His detail was perfect, and whether he was working in the wards, or bringing an heir to millions into the world, his work was performed in that same thorough, careful and successful way. To see him work was to realize that he was an artist of the highest scientific type.

CORRESPONDENCE.

OUR PARIS LETTER.

(From Our Special Correspondent.)

Paris, February 22, 1902.

PROFESSOR GILBERT NAMED PROFESSOR OF THERAPEUTICS—THE USE OF ELECTRICITY IN SPRAINS—ADULTERATION OF MILK IN PARIS—SERUM OF TRUNECEK.

Dr. Gilbert, one of the best known of the younger professors of the Faculty of Medicine, has just been named professor of therapeutics, a position which has been occupied several years by Professor Landouzy, who has acquired much fame on account of his discoveries in neurology. Dr. Landouzy, while occupying the chair of therapeutics, insisted on the distinction that existed between treating diseases and treating patients. He had a set of aphorisms to explain his ideas on therapeutics which were the following: Therapeutics as a science should always be clinical, pathogenic, physiological, opportunist; clinical as to its sources of information, pathogenic in its indications, physiological in the methods used, and lastly opportunist in its decisions. Professor Landouzy has been given the chair of clinical medicine, vacated by Professor Jaccoud, the author of the treatise of medicine which preceded that of Dieulafoy.

Drs. Charrier and Planet have called the attention of the French medical public to the advantages of the use of electricity in sprains. This treatment is hardly men-

tioned in most treatises on electrotherapeutics, though some English authors speak of it without, however, giving any clear indication of the method to be employed. Apostoli recommended using the faradic current with very rapid interruptions. The electrodes should be of carbon covered with chamois skin, and, while the positive tampon remains in one position, the negative one is moved all over the painful area. The results would seem to be surprising; after five minutes the patient is able to get up and walk, the pain having ceased for the time being. Two applications should be made daily, and the patient told to walk as soon as possible.

There has been of late quite a discussion not only among medical men, but also in the general public as to the milk supply of the City of Paris. The *Matin*, a prominent daily, started it by describing the various methods of milk adulteration, and asking for the establishment of a League for the Defense of Human Life, the members of which would be requested to contribute only one, two, or three francs. They could send samples of the milk they received to a special laboratory, where the milk would be analyzed. If the report was adverse, the seller would be prosecuted and the damages awarded would be handed over to the member who had given in the sample. It seems that the City of Paris uses 700,000 liters of milk daily; 200,000 liters are furnished by the dairies included in the metropolis, and 500,000 are brought from the country. The first-mentioned varieties would seem to be the best, as strict supervision is exercised in order to prevent the use of tuberculosis cows. Moreover, there is less chance of the milk being adulterated, as it can be bought directly. It is quite different with milk brought from the country, which is first collected by certain farmers and handed over to collectors, who send it to Paris, where it is distributed by other milkmen to the retailer. The milk is therefore handled by four different groups of men, who try to make as much profit as possible, so that milk, which costs in the country only nine to eleven centimes, is sold at forty centimes to a franc in Paris.

Still another serum has been placed upon the market and is being extensively advertised. It is called the serum of Trunecek and is supposed to produce most remarkable results in a variety of conditions. Two articles on this serum have appeared in the *Presse Médicale*, signed by a Dr. Leopold-Lévi, and prospectuses have been sent out by a well-known druggist in Paris. It is a mooted question whether this latter preparation will take on as well as cacodylate of soda and lecithine, which were the fashionable drugs last year.

Dr. Poirier, who is one of the best known operators in Paris, has just reported his first death from chloroform. The patient was an emaciated old woman suffering from cancer of the stomach. Some twenty-five minutes after the operation had been begun, the heart suddenly stopped beating. The writer of this letter happened to be in Dr. Poirier's service a little over a month ago, when he was examining this woman and trying a new apparatus for gastroscopy, when Dr. Poirier made the remark that he had never lost a patient from chloroform.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK CITY.

Stated Meeting, Held January 25, 1902.

Palmer C. Cole, M.D., Chairman *pro tem.*

Gangrene of Genitalia.—Dr. Ramon Guiteras reported the case of a young man, aged twenty-three, in his service at the City Hospital, who came under treatment suffering from an extremely raw and inflamed condition of his genitals. This inflammatory condition had lasted for some time and all the superficial skin of the testes and the lower part of the penis had sloughed away, the penis being uncovered from the corona to a point about half an inch from the pubis, the testes bare, drawn up against the opening of the external canal and covered with a whitish, sticky exudate. By a series of flaps of skin obtained from perineum and the adductor surfaces of the thighs, the genitalia were covered successfully after careful sterilization of the tissues. The plastic operation proved very satisfactory and the result enables the man to go about his occupation as before.. After the operation some details of the man's previous condition were obtained from himself and friends. He had been a laborer in a brickyard; and the first symptom of his ailment seems to have been an enormous swelling of the scrotum, which was very painful, tender and the size of a baby's head. The physician who was called in laid open the scrotum freely and found that, as the result of the pressure on the tissues, certain parts of the skin were already gangrenous. Charcoal poultices were applied freely and the tissues continued to slough for several weeks. It seems evident that the origin of the condition was probably an extravasation of urine into the scrotum. There is no history in the case of a catheter having been employed, but Dr. Guiteras has seen other cases in which this seemed to be the occasion for the gangrene. There is the possibility of severe trauma setting up such a condition, but there is no history of any accident in this case. Such gangrenous sloughing of tissues may occur rather readily in diabetic patients, and sometimes in tuberculous patients. One might think of a phagedenic process in such a case, but a phagedenic sore would not involve the cutaneous tissues alone, but would spread deeper and produce more serious consequences. It seems preferable always to do plastic work in covering up the testicles than to leave these organs to become covered by granulation tissues. Dr. Guiteras has seen the enlarged scrotum of patients suffering from elephantiasis submitted to surgical treatment. In these cases the affected tissues are simply dissected away and the testicles are allowed to become gradually covered by granulations. In these patients, however, adhesions are likely to form, the scar becomes painful and irritable, movement is interfered with and the genitals are held by cicatricial tissue as in a vise.

Unaccountable Asthma.—Dr. John H. Huddleston describes a case in which the patient suffered from what were presumably asthmatic attacks, until the end of the case revealed malignant disease as the basis of the symptoms. The patient was a man aged fifty-six years, a widower, by occupation a clerk, coming of a long-lived family, and without any tuberculous or malignant history. About twelve years ago, according to his own story, he suffered from locomotor ataxia; he was, however, cured of this condition by a nerve specialist in nine months. He had the habit of taking four or five whiskies a day, but could scarcely be said to be frequently under the influence of liquor. His symptoms consisted of asthmatic attacks with cough, more at night but continuing also during the day. There was prolonged expiration and some squeaking râles on inspiration. Each day he expectorated two to four ounces of frothy sputum. He experienced considerable dyspnea even after moderate exertion, and this dyspnea was marked not only during expiration, but during inspiration. He was put upon iodide of potassium, but the drug did not relieve his symptoms. Asthmatic cigarettes also failed to give him any relief. Morphine in doses of one-eighth of a grain was the best remedy and the most satisfactory during his asth-

matic attacks. After being under treatment for some weeks he complained of difficulty in swallowing. This, however, seemed to be mainly subjective, for when asked to do so in the physician's presence he was able to swallow various food substances without great inconvenience. He complained considerably of gas in his stomach and after awhile refused to take any but liquid food. This gave rise to some alarm and the diagnosis of the case seemed to lie between hysteria, nervous dyspepsia and an organic lesion of the esophagus. A consultant who was called in to see the case thought the patient might be suffering from an aneurism. There were, however, none of the ordinary physical signs of this condition. Two months after his taking to liquid food there was considerably more expectoration than before. The patient used to cough up from eight to ten ounces of frothy suptum during the twenty-four hours. As his symptoms continued to increase and his dyspnea was a source of great discomfort, while he was constantly losing in weight, another consultant was summoned.

Diagnosis and Autopsy.—Dr. Janeway found on examination of the patient an evidently fresh fracture of the eighth rib. No reason could be found for the existence of this fracture. There had been no trauma or accident of any kind. After careful examination Dr. Janeway gave the opinion that the patient was suffering from possible carcinoma of the esophagus. Nothing could be done for the relief of the symptoms, the dyspnea increased to orthopnea, and the patient died four days later. At the autopsy an ulcerating carcinoma of the esophagus was found, involving some four inches of the esophageal tube. There was no stricture of the esophagus in the neighborhood of the malignant growth. A finger could very easily be passed through it and the difficulty in swallowing was evidently a nervous reflex, rather than an actual mechanical obstruction. The carcinomatous growth had spread by contiguity to the larynx, and a papillary carcinoma about half an inch in diameter filled up the lumen of the larynx. There was at no time any external evidence of tumor and there seems to have been no way in which the presence of the growth could have been diagnosed with certainty during the life of the patient.

Cervical Cancer in Pregnancy.—Dr. Egbert H. Grandin reported a case of cancer of the cervix uteri in which the size and position of the malignant growth would seem to preclude the possibility of conception taking place. The patient was an Italian woman who came to the hospital suffering from constant hemorrhage. The entire vaginal portion of the cervix had disappeared and the uterine tissues seemed completely infiltrated with the malignant growth. The uterus was found large and movable and there seemed to be no involvement of parametric tissues. It was resolved, therefore, to do a complete hysterectomy by the abdominal route. The uterus was found to be distinctly enlarged and within its cavity there was a fetus of about five months. In such cases, that is, in cancerous involvement of the body of the uterus, hysterectomy is the surgical indication, and yet operation seems almost useless since there are always recurrences. Dr. Grandin does not think that he has ever seen a case in which recurrence did not take place after hysterectomy for cancer of the uterus.

Extra-Uterine Pregnancy Without Classical Symptoms.—Dr. Grandin gave the details of a case in which the patient suffered from extra-uterine pregnancy, though none of the classical symptoms set down in the text-books as characteristics of that condition were present. Careful taking of the history failed to elicit any account of hemorrhage after an interval of amenorrhea. The pain was not of the intense prostrating character that is usually spoken of, but was rather spasmodic and resembled colicky pains of the intestines. No portions of the decidua were passed. Menstruation had been regular except the last; this had occurred at the regular time, but there was less flow than usual. Normally it lasted about six days, but this time it persisted for only three. This is not an unusual symptom and must sometimes give rise to the suspicion of extra-uterine pregnancy. The amount of menstrual flow was very small. Examination showed the presence of a small uterus, with a mass lying free in front of it thought to be a hydrosalpinx, and operation was advised because the pains had become almost constant and were a source of great discomfort. It was not until beating vessels were recognized in the tumor at a subsequent examination, more than a week later, that extra-uterine pregnancy was diagnosed and the operation performed.

Pseudopregnancy.—Dr. Grandin was recently called in to see a woman who, it was supposed, was about to be confined. She presented an enlarged abdomen and enlarged breasts and the history showed the characteristic vomiting of pregnacy and continued amenorrhea for about the usual length of pregnancy. Examination, however, showed a hard cervix and a small uterus. Dr. Grandin gave an anesthetic, and under its influence the sphincters collapsed, the windy tumor of the stomach disappeared and the imaginary baby was delivered.

Imaginary Labor.—Dr. Brewer related the case of a woman supposed to be in labor, whom he had recently seen in a lying-in-hospital. She had had three children before and was suffering apparently from regular normal labor pains, which occurred about every five minutes. The cervix was found to be hard, however, the uterus was not enlarged and no fetal heart sounds could be heard. After a time the woman was persuaded that she was not in labor, her pains ceased and she left the hospital. Three days later she was brought in again in an ambulance, once more with characteristic labor pains, after having excited the sympathy of her neighbors at home. She turned up at another hospital for the third time within two weeks and seemed finally to have been convinced that the symptoms of labor were only imaginary. Dr. Brewer made it his business to follow up the case and inquired of her sister with regard to the condition of the patient. The sister assured him that the woman had been once more taken with labor pains and had been delivered of a healthy child, by a private physician. In order to make the records of the case complete he asked the name of the physician, whom he looked up but found that he had died several years previously.

Environment of Imaginary Pregnancy.—Dr. Grandin, in discussing Dr. Brewer's case, said that the patients who suffer from imaginary pregnancy usually occupy very definite environment; they are mainly widows who have every reason to fear that they may be pregnant and to whom memory serves as a stimulus for the repetition of the symptoms that occurred during former genuine pregnancies. Dr. Grandin has recently had two such cases and it was extremely difficult to persuade the patients that there was no pregnancy in progress. Occasionally these symptoms occur in elderly unmarried women, when, however, the symptoms are more anomalous and do not resemble the signs of ordinary pregnancy so closely. Frequently the only differential diagnosis possible must be made after a bimanual examination. As a rule, the examining finger comes in contact at once with a hard cervex and this is of itself sufficient to decide against the existence of pregnancy.

Pregnancy and Exstrophy of the Bladder.—Dr. A.

Palmer Dudley in commenting upon Dr. Grandin's case of pregnacy in a patient suffering from carcinoma of the cervex uteri and the consequent necessity for the spermatozoa to penetrate the foul, ulcerous mass, detailed a case in which there would seem to be even less possibility of pregnancy occurring. The patient suffered from stone in the bladder, which was removed with the forceps, causing an exstrophy of the bladder into the vagina. The orifices of both ureters could be seen in the vagina and there was a constant flow of urine from the parts. Usually spermatozoa are said to be affected very seriously by such acid secretions as urine, but in this case they succeeded in finding their way into the uterus and impregnated the ovum.

Phantom Tumors.—Dr. Dudley has recently seen two cases of characteristic phantom tumor. One of the patients was a young Irish woman, twenty-seven years of age, whom Dr. Dudley found noisily complaining of what seemed to be regular labor pains. As the cervex was hard and the uterus of normal size, Dr. Dudley at once declared that she was not pregnant and not in labor. The result of this surprising declaration to the patient was that she got out of bed very quickly and Dr. Dudley got out of the house very rapidly. Subsequent developments, however, proved not only to the friends of the patient, but even to the patient herself that she had not been pregnant. A certain number of these cases of imaginary pregnacy are due, in Dr. Dudley's opinion, to a sudden large accumulation of fat in the abdominal wall and cavity of certain women. This is a special large-celled fat, growing with particular rapidity, and when the patient walks it produces a certain joggling motion in the abdominal wall that seems to be the ground for the imaginary idea of fetal movements. Of course, occasionally, the phantom tumors are really due to nothing more than an accumulation of gas in the intestines, which patients seem to have the power of retaining for a long time when under the influence of certain mental ideas, and the consequence is a persistent tumor that constitutes the best objective sign of the supposed pregnancy.

Measles Before Six Months.—Dr. Edward M. Foote said he had recently consulted a prominent specialist with regard to measles in children, and had been told that the disease practically never occurs before the age of six months. He asked for the experience of others with regard to the occurrence of the disease in early infancy.

Dr. Bryant said that in his connection with the Hospital for Contagious Diseases he had seen a number of cases of measles in children under six months of age. Besides this he has seen a number of relapses of the disease and thinks that measles provides the least protection against a second attack of any of the infectious diseases of childhood. In one case Dr. Bryant had seen five relapses of measles, after each of which the patient was free from rash for at least one week before the new crop of measles lesions appeared. He has also seen patients suffer successively two and three attacks of the disease.

Second Attacks of Syphilis.—Dr. Sturgis said that he has seen several cases of second attack of syphilis occur under his own observation. He is sure in these cases that the patients after an interval of several years had a repetition of their syphilitic symptoms running through all the so-called stages from primary to secondary lesions, showing that there had been a reinfection. One of his patients was a young man who had a light attack of syphilis at first, and some six years later a severe attack. The other patient was older and had severe syphilis at first and later a comparatively mild attack. The most interesting feature of these second attacks is the fact that they give absolute assurance that under certain circumstances the disease is completely cured; a second attack would not occur so long as any remnant of the previous infection remained in the system. Such evidence as this is of special importance at the present moment, when there are exaggerated notions of the incurability of syphilis; many eminent specialists incline to the opinion that years of medication are required for its eradication; some practically advise discontinuous medication at intervals for most of the rest of life. This makes the question of syphilitic therapy rather discouraging and the assurance of cure in certain cases is, to say the least, a consolation.

Treatment of Syphilis.—Dr. Eugene Fuller said that syphilis is a disease that must always be treated with respect. It is at least as serious a pathological condition as tuberculosis in any of its forms, and the more one learns of its pathology, the more serious has its significance become. Dermatologists are prone to make less of it than is perhaps justified by the ultimate results in many cases. Neurologists, on the other hand, who see only its effect on the central nervous system, never slight it. There is no doubt that it affects all organs; many more cases of liver trouble than are usually attributed to it are really due to its existence in the system. The fact of the matter is that most patients are not treated with sufficient thoroughness; after five or six months patients see no further symptoms and can find no reason for continuance of treatment or for further visits to the physician. They conclude that the doctor is working them, lose confidence in medicine and the result is the development of the serious sequelæ of the disease a little later.

Syphilis and Infant Mortality.—Dr. Grandin said that the importance of syphilis in women's diseases and in obstetrics could scarcely be exaggerated. Not only syphilis but the other venereal diseases are extremely important. The gynecologist who sees serious lesions of the female genital tract and the obstetrician who assists at the birth of dead children feel strongly the necessity for regulation that would make these diseases less prevalent than at present.

Dr. Dudley said that the results of syphilis in the newborn were of themselves sufficient to make physicians realize the awful importance of the disease. He knows of thirteen children who have been lost in two families because of two syphilitic fathers. Syphilis is undoubtedly worse than tuberculosis, and at the present time, when so much is being done to prevent the spread of tuberculosis, physicians should be ready to begin the crusade for the prevention of syphilis.

Dr. Sturgis said that the neurologists are daft on the subject of nervous syphilis. The easiest argument in the world to make is *post hoc ergo propter hoc*, and it is the argument most liable to mistake. It is conceded that syphilis may affect every tissue, yet it is seldom a fatal disease and it is by no means so unamenable to treatment as is often said. It is not easy to differentiate tuberculosis and syphilis and some cases are attributed to syphilis undeservedly. Women suffer seriously from syphilis, but do not die from it, though it must be confessed that child mortality is greatly increased by it. Drinking habits and syphilis often go together, and the supposed serious sequelæ of syphilis are often really due to alcoholism.

RUSH MEDICAL SOCIETY OF CHICAGO.

Stated Meeting, Held February 3, 902.

Dr. Dickerman in the Chair.

Huntington's Chorea.—Dr. Harold N. Moyer reported four cases of Huntington's chorea. Two of these presented a family history in which the disease had occurred in a direct line for four generations, as

well as appearing in numerous collateral branches. He referred to Huntington's original paper, published in 1872, and stated his belief that one of his patients, who was born in southeastern New York, probably belonged to one of the original "megrim families" upon which Huntington's description was based. Huntington's chorea is a variety of the progressive degenerative chorea of adults, which is only to be distinguished from the latter by its family type.

Dr. George W. Hall, in discussing Dr. Moyer's paper, said that there is nothing more interesting in medicine than the study of nervous diseases and especially their history. It is, however, unfortunate that the disease under discussion has been named Huntington's chorea. It differs in a great many ways from the chorea of childhood as far as its pathology is concerned and Huntington, as has been stated, was really not the first to describe the disease. Waters of New York, in a letter to another physician, mentioned practically the diagnostic points of this form of chorea thirty years before Huntington published his article, which was read before the Meigs and Mason Medical Society in Ohio in 1872. Waters in his letter to Dr. Dunglison mentioned the four following points, *viz.*, (1) the pronounced hereditary tendency of this form of chorea; (2) its rarity before age of forty-five; (3) its incurability; (4) its tendency to dementia. Huntington believed that this disease was peculiar to a certain locality in New York and he noted the heredity, the gradual tendency to progress as well as the tendency to suicide or dementia. Dr. Moyer states that there has been no variation from Huntington's statements down to the present time. Huntington made an unconditioned statement that when one generation was skipped, this disease never occurred in any succeeding generation, or, to use his words, that is was handed down as an heirloom from one generation to another, differing in this respect from syphilis and tuberculosis. Recent literature contains records of cases in which one generation has been skipped and the disease again presented itself. And if he noted correctly, one of Dr. Moyer's cases presents such a history. Dana, however, records a case, a male, aged thirty-seven, whose great-great-grandmother, great-grandmother, grandmother and mother were affected similarly. Dr. Moyer, he believed, made the statement that the symptoms and choreiform movements could not be distinguished from those of childhood. The movements certainly differ from those of Sydenham's chorea in that they are coarser, more irregular, incoordinate and lack rhythm. The progressive tendency toward dementia is noted in most of the cases reported. Osler states that it is a neurodegenerative disorder, that the cerebral changes are very similar to those found in chronic dementia—a meningo-encephalitis. Dr. Good of Michigan, who made a very complete postmortem report on a case observed by him in one of the Michigan insane hospitals, found considerable atrophy of the brain convolutions with marked adhesions of the brain coverings, changes in the vascular system and great cell degeneration.

Anatomy of the Ear.—Dr. George E. Shambaugh demonstrated a series of anatomical preparations of the ear. The study of the anatomy of the ear is in many respects not an easy matter. The ear has a very complicated structure and the parts are crowded together into such a small space, while the whole is encased in the solid bony walls of the temporal bone, that it makes their study by the ordinary methods of dissection quite unsatisfactory. The study which the student of medicine usually puts on the anatomy of the ear in the dissecting-room consists of chiseling a hole into the pneumatic spaces of the mastoid process. What facts the student may have at his command of the anatomy of the ear he has gathered from descriptions in textbooks. Knowledge acquired in this way is not the real, definite knowledge that the student can apply readily when studying clinically the diseases of a part. The most serious problem one has to contend with in giving clinical instruction in otology is this lack, on the part of the student, of any definite knowledge of the anatomy of the ear. A clear, definite mental picture of the structure of the organ of hearing is best acquired by the study of actual anatomical preparations of the ear made especially to bring out the various parts. Such a set of preparations were shown. The set includes the following: (1) A series of sections of the dried temporal bone cut through the various planes so as to bring out clearly the different parts. (2) A similar series of moist preparations with the soft parts intact, including preparations of the external ear and the Eustachian tube. (3) Corrosive casts made of Wood's metal. These casts are specially useful for showing the structure of cavities like the spaces in the temporal bone occupied by the organ of hearing. (4) Casts of the labyrinth alone and others of all the spaces in the temporal bone, including the labyrinth as well as the mastoid cells and the external meatus. (5) Pen-drawings of most of the preparations made just twice the size of the actual preparation, with each point of interest labeled with its correct term according to the B. N. A. system. By comparing the preparation with the drawing, the student can, without any difficulty, pick out any point on the preparation and get its correct name.

The specimens were highly commended by Prof. Holtz and Dr. Dickerman as being of great value in teaching. Dr. Moyer spoke of them as being of special value in demonstrating the anatomical relations of the ear to the brain.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 8, 1902.

The Vice-President, George G. Peabody, M.D., in the Chair.

The order of business included the discussion of the resolutions on the action of the Treasury Department declaring pulmonary tuberculosis "a dangerous contagious disease" and debarring consumptive aliens, rich and poor, from entering the country.

In discussing the resolution Dr. Knopf said that to declare consumption a dangerously contagious disease is to advise public opinion that even incipient tuberculosis must be sedulously avoided. As a consequence patients suffering from early tuberculosis will fear to consult a physician because of the dread of social ostracism if it be once known that they are suffering from the malady. Practically the only chance for the successful treatment of tuberculosis is during the incipient period. In our American sanatoria seventy-five per cent. of the incipient cases are discharged cured. The resolutions offered do not counsel the admission of pauper immigrants suffering from tuberculosis nor condemn the Treasury Department for refusing to admit them. Emigrants, however, who are well able to take care of themselves, or to provide for their care should not be debarred for fear that they will prove centers for the distribution of tuberculosis.

Dangerous Contagion.—To say that a disease is dangerously contagious implies that mere contact with a patient suffering from it may cause the development of the disease in another. This is not true for tuberculosis, and only long exposure to respiratory infection will bring about its development in those who live close to tuberculous patients. There is no danger even from

this form of infection if proper precautions of cleanliness are observed. It is evident then that the Treasury Department resolution is exaggerated and not founded on scientific observation nor on experiment. The Academy of Medicine by adopting these resolutions will state the proper position that the medical profession assumes on this subject and will prevent an outbreak of phthisiophobia that might easily have serious consequences.

Presumption of Small Representation.—Dr. Quimby said it would be presumptuous to let the few members of the Academy present—not more than fifty or sixty in all—set themselves up as the representatives of the 10,000 medical men in New York. The Treasury Department decision is in accordance with recent advances in knowledge of tuberculosis. These patients are a source of danger to others. If the paper must be stripped from the walls of rooms in which tuberculous patients have lived and it is declared that only fire can really accomplish the purpose of properly cleansing such rooms, the logical outcome of this knowledge must be faced and the surveillance of tuberculous patients must be insisted on. Otherwise medical men stultify themselves before the public by announcing one thing in theory and then fearing to carry out the practical conclusions.

Infection and Contagion.—Dr. William H. Thomson said that years ago he proposed a distinction in the significance of the two words infection and contagion. Infectious diseases were those due to micro-organismal activity. Contagious diseases were those in which proximity of the well to the sick brought on the disease. There is an entire class of infectious diseases that are non-contagious; of these typhoid fever is a good example. Years ago the Boston Health Board declared cholera non-contagious and said that it was due to a miasm that spread through the air; hence measures need not be taken to guard against it. It is unscientific to label tuberculosis contagious and the New York Academy of Medicine compels the Board of Health to eliminate the word contagious from their rescript with regard to the disease. It is a reproach to the profession that the Treasury decision should stand without protest.

Dr. Dana said that the resolutions in his opinion should not be passed, as was proposed, but should be referred to an authoritative committee. This would stamp the action of the Academy as thoroughly official and considerate.

The resolutions proposed by Dr. Knopf were then carried by vote of the members present.

On motion it was also resolved that a copy of these resolutions should be sent to the Treasury Department in formal manner and also to the State medical organizations of New York.

Tuberculosis Wards on Blackwell's Island.—The report of the Committee appointed by the Academy to examine the buildings on Blackwell's Island, recently abandoned by the State Hospital for the Insane, to decide as to their possible usefulness as wards for tuberculous patients, was accepted. They consider that these buildings will be suitable for advanced cases of consumption and only for these after certain improvements suggested by the Committee have been made in them. The Committee consider that these buildings should be looked upon only as a temporary provision for tuberculous patients and that their occupation should not delay the arrangement of other ways of taking care of the tuberculous.

Phenomenon of Inhibition.—Dr. S. J. Meltzer read a paper on the phenomenon of inhibition and its possibilities in pathology, especially in its relation to myxedema and exophthalmic goiter. Dr. Meltzer said that the demonstration of the power of the vagus nerve over the heart opened up the whole subject of inhibition. Stimulation of the inhibitory fibers produce a number of effects upon the heart; it lessens the power of the organ to contract, it diminishes the tonus of the cardiac muscle; it diminishes its excitability and its capability of responding to stimuli; it abolishes conductivity within the heart structures, and, finally, it changes the electrical reaction of the cardiac muscle. Stimulation of the accelerator fibers produces just the opposite set of effects. This picture of the influence of inhibition gives the best general idea of the character of this property of nerve tissue influence that can be formulated. Inhibition may be exercised over nearly every tissue in the body. Function may also be inhibited and secretions prevented. The influence on other tissues is almost as extensive as on the heart, which is the type of this form of physiological effect. The most important characteristic is the omnipotence of inhibition over all cellular tissues.

Irritability used to be considered the most specific and essential characteristic of vital tissues. It is now known that inhibition is quite as extensive a property of tissues as irritability. All the connective tissues are irritable, which, as will be seen in the course of the discussion, may mean either excitation or inhibition. During life rest is as vital for tissues as activity. Most of the states of tissue existence lying between the exercise of function and rest are the resultant of the two forces, excitation and inhibition. Inhibition has sometimes been considered the process of anabolism, the building up of tissues. On the other hand, excitation has been considered coextensive with metabolism, the pulling down of tissues. Neither of these definitions is complete, however, and anabolism may proceed apart from inhibition.

If the two antagonistic nerves to the heart, the inhibitory and accelerator nervous fibers be stimulated, the only effect noticed immediately is one of inhibition. This inhibition is only a little less in quantity than if the vagus were stimulated alone. The accelerator nerve as an antagonist to the inhibitory nerve does not produce much effect. The effect of stimulation of the inhibitory nerve, however, soon passes off. The stimulation of the accelerator continues for some time afterward and can be noted when the inhibitory effect has completely ceased. The inhibitory nerves become exhausted much sooner than the accelerator nerves.

Motor Nerves and Inhibition.—Skeletal muscles respond to stimulation and it is often asked why the effect of inhibition is not noticed. As a matter of fact, the contraction of any muscle is accompanied by an inhibition of the tonus of the antagonistic muscles. Stimulation of the flexors, for instance, from the brain cortex inhibits the tonus of the exterior muscles in the same limb. At times in addition to these antagonistic actions a partial set of opposite effects are noticed on the other side of the body. This crossed innervation can be noticed in many functions of the animal organism.

Inhibition and Biliary Secretion.—The flow of bile into the intestine is one of the physiological mysteries that have not as yet been entirely explained. The splanchnic fibers of the vagus distributed to the intestine seem to act when irritated by the presence of food in the duodenum as inhibitors to the muscles associated with Vater's papilla, through which the biliary and pancreatic secretions are emptied into the intestine. This is not, however, the only action necessary in order to secure the presence of bile in the intestine. Some nervous reflex must be communicated to the gall-bladder so as to produce contraction in and evacuation of its contents. Needless to say these various actions

require a very delicately adjusted nervous mechanism which may easily get out of order; when it does, interference with the free flow of bile results. It is evident, then, that there are many causes besides catarrhal conditions of the biliary tract and biliary calculus that may prevent the flow of bile. Certain reflex nervous conditions may readily simulate mechanical obstruction of various kinds; undoubtedly, the emotional icterus so often described by French writers is due to interference with the delicate nervous mechanism that controls the flow of bile. Many of the reported cases of catarrhal icterus are, in Dr. Meltzer's opinion, due to reflex interference with the inhibitory and excitator apparatus of biliary flow. When there has been preceding gastro-intestinal catarrh, the diagnosis of catraahal icterus is well justified. When no symptoms of gastro-intestinal catarrh have occurred, the assumption of the existence of a biliary catarrh is at least suspicious.

Gastric Disturbances and Nervous Reflexes.—When gastric digestion is seriously disturbed, the gastric contents passed on to the intestine may prove entirely unsuitable for awakening the reflex nervous influences on which biliary secretion depends. When the chyme, for instance, has been crudely prepared, or when it is ejected from the stomach, covered by mucus, its presence may fail utterly to give the necessary reflex stimulation for the biliary apparatus. The problem of inhibition and of excitation in this part of the gastro-intestinal tract is extremely intricate, but its solution will enable the physcian to realize the etiology of many conditions that are now obscure, though certain words employed to explain them seem to give some idea of the true cause at work.

Inhibition and Colic.—Colic is usually considered to be due to a spasm of a mucous canal. This explanation, however, scarcely serves to make clear the intense twisting and sometimes increasing pain that characterizes colicky attacks. The real explanation seems to be that colic occurs when two parts of the intestinal canal are strongly contracted. These two portions are not far apart and while the lower one has a constant position the upper spasmodic contracture moves downward; this forces the gas and other contents of the intestine against the lower contracted portion and causes the painful distention of the intestine which gives rise to colic. This pain increases, rises to an acme and then is relieved to recur in a similar way when peristalsis causes another wave of contraction to pass downward. The contracted ring on which colic really depends is due to an inhibition of the motor muscles of the intestine at this point and a stimulation of the circular fibers.

Family Periodic Paralysis.—There are in the literature now about forty cases of patients suffering from periodical paralysis. These paralyses occur especially in members of certain families and last for from a few hours to a few days. During the existence of the paralysis there is a total absence of irritability of the muscles affected; neither mechanical nor electrical stimuli have any effect upon them. The paralysis would seem to be due to a state of inhibition which for the time being obliterates all nervous function in connection with the affected part.

Myasthenia Gravis.—This is a condition of paralysis consisting of a group of symptoms which closely resemble those of a bulbar paralysis. The muscles most frequently affected are those of the face, especially the eyes, head and neck, with difficulty of swallowing, defective articulation and inability to support the head. In the cases reported so far no lesion of the nervous system has been found, though most of the cases have proved fatal. Dr. Meltzer is inclined to think that this condition is due to an inhibition of special sets of muscles. The affection of various muscles fluctuates as if it were merely neurotic, but its fatality shows that some serious underlying condition exists.

Myxedema and Graves' Disease.—Dr. Meltzer considers these two affections as contrasting examples of the disturbance of normal equilibrium of inhibition and excitation as connected with the thyroid gland. Myxedema represents a diseased excitation of the tissue metabolism in favor of inhibition; Graves' disease is a corresponding disturbance of tissue metabolism in favor of excitation. In myxedema the heart beats are smaller and are usually slower, the bowels are sluggish, the sweat-glands are inhibited, the mental processes are rendered slow, muscular motion is slower than normal, the temperature is lowered and there is a general lack of systemic tonicity. On the contrary, in Graves' disease the heart beats fast and high, diarrhea is apt to be present partly as a result of increased peristalsis and partly because of increase of glandular secretion of the intestines; all other glandular structures are stimulated; the sweat and urine are more plentiful; the intentional tremor so characteristic of the disease is really due to the fact that there is an excitation of the flexor muscles with the failure of inhibition of the extensor muscles which prevents that simultaneous action that would keep the parts at rest.

Exophthalmic Goiter and Inhibition.—Most of the characteristic eye symptoms of Graves' disease are associated with a state of nervous excitation. Stellwag's symptom, for instance, represent an increase of tonus of the levator muscle of the upper eyelid. The exophthalmos itself is due, at least in part, to valvular dilatation behind the eyeball. Moebius' symptom is due to overstimulation of certain of the internal eye-muscles that prevent proper convergence in association with near vision. There would seem to be a set of symptoms in the peripheral vascular system that contradict the idea of overstimulation. The peripheral capillaries are all relaxed in Graves' disease. This can be readily recognized from the readiness of the patient to blush easily and from the prompt occurrence of the tache cérébrale when the skin is irritated even slightly. These signs are an index of peripheral vasodilatation. It is very hard to reconcile them with the existence of a stage of excitation in peripheral nerves generally. It must be remembered, however, that the important reservoirs of the vascular system are the large abdominal blood-vessels. Within the abdomen the state of excitation causes a narrowing of the large intestinal blood-vessels and the blood thus forced into other paths finds its most likely way into the peripheral capillaries. Consequently, these become dilated with blood, not as the result of true dilatation, but of overbalance in the circulation due to the closure of internal blood-vessels.

Treatment of Graves' Disease.—There is no doubt that the most effective remedy in Graves' disease is the phosphates. Sodium phosphate is probably the most generally useful remedy in the condition. There is some specific relation between the administration of the phosphates and the production of certain forms of nervous inhibition; this seems to be the secret of the true effect of the phosphates. This same drug, however, has very little, if any, effect upon the tremor due to senility or upon alcoholic tremor, though these forms of tremor would seem to be sufficiently closely allied to the intentional tremor of Graves' disease to be associated with it in therapeutics.

Inhibition an Accepted Theory.—Dr. Charles L. Dana said that the rôle of inhibition in nervous diseases is a widely accepted theory and neurologists generally have come to recognize it as an important funda-

mental influence in many nervous affections. It is comparatively easy to accept inhibition theories of nervous diseases with regard to peripheral nervous affections; with regard to nervous centers of inhibition, however, there is no good reason for acceptance. It is a fascinating theory, for example, to explain periodic palsy by inhibition of nervous impulses to certain muscles. Myasthenia gravis and especially the myasthenic attacks which are so characteristic of this disease certainly receive their most satisfactory explanation on the ground that they are inhibitory spasms, a sort of inhibitory tic, an affection the very opposite, by analogy at least, of chorea and the convulsive tic. Of late years, neurologists have come to realize that Graves' disease has its best explanation not on the theory that it is due to essential thyroidism, but to a vasomotor excitation of the bulb. Dr. Meltzer's ingenious explanation of the cutaneous vasodilatation existing in the disease is most plausible. It enables the neurologist to realize how notwithstanding the symptoms of excitation so prominent in the disease as regards the internal organs, there is relaxation in the peripheral capillaries.

Inhibition as Nervous Influence.—Dr. Thomson said that inhibition undoubtedly plays a more important rôle in physiology than has been thought. Inhibition is always at work. Every nervous function is controlled by others and healthy vitality is the resultant of inhibitory influences upon one another with due coördination. Even in the higher rational sphere, the influence of inhibition is very noticeable; dreams are made up of ideas and sense perceptions and sensation, but these follow one another without control or discipline, hence are absurd. True thought is properly checked and controlled by inhibitory influences. The eye must always be controlled and disciplined, or objects seen would be completely misunderstood. Since inhibition is so prominent in the higher things of human life, it would be only natural to expect that it would exert a dominant influence on the more properly physical activities.

Graves' Disease and Myxedema.—Graves' disease undoubtedly represents a paralysis of inhibition and the consequent domination of uncontrolled excitation. Dr. Thomson does not think, however, that the opposite nervous condition is the true explanation of myxedema. It is not an increase of inhibition that causes the symptoms of myxedema, but it is rather a lessening of all the physical activities on which life depends. It is as if the fires were banked underneath the engines and the amount of energy supplied to the machine lessened. Inhibition is an active quality. All activity is lessened in myxedema by the presence in all cellular structures of the substance that hampers metabolism, interferes with function, disturbs reflexes, and diminishes all vital activity.

Centers of Inhibition.—Dr. Meltzer in closing the discussion said that it seems almost hopeless to look for separate centers for inhibition, though this was the custom among physiological neurologists some years ago. Inhibitory centers seem to be associated with other motor and secretory centers and thus produce their effects by coördination and not by direct interference.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held February 10, 1902.

The Vice-President, William McCollum, M.D., in the Chair.

Collective Investigation of Disease.—The Vice-President, Dr. McCollum, introduced the President-Elect, Dr. Andrew H. Smith, who delivered the annual address. In the course of it he said that he would like to suggest that a practice of collective investigation might profitably be engrafted upon the other work of the Society, not in a very formal way, but merely by having under consideration two or three topics upon which the members would be invited to accumulate observations as opportunity offered. When a sufficient body of observed facts had been secured they could be made the subject of a report. At the present time, so far as he was aware, there was no other society in New York engaged in a work of this kind, and the vast city, with the teeming millions of its five boroughs, in all of which the Association had so many able representatives, certainly offered a most inviting and fruitful field for such investigations.

Specific Medication.—Dr. Smith then took up the special topic of the evening, specific medication. Having referred to what is termed treating the patient instead of the disease, he said there were morbid states which evidently are but the working of a foreign agent which has obtained a lodgment in the body, which latter serves merely as the theater of its operations. The activity of this agent then constitutes the disease, and the disease will continue so long as the morbific agent remains active. Such a disease is called specific, and the disease itself, as distinguished from the patient, calls for treatment. The treatment in such a case necessarily implies the employment of some remedial agent having the power of antagonising the nervous principle at work in the system. This antagonism may be either chemical or vital in its mode of action, and more commonly it is the latter. As yet, the list of diseases, such as malaria, rheumatism, and syphilis, for which universally accepted specifics exist is very limited. It is not claimed that a specific shall be successful in every case. The most required is that in uncomplicated cases, and under proper conditions, a cure may be expected, or, at least, that the disease may be held in check so long as the remedy is continued. It may be said, in general terms, that the prospect is favorable for an increase in the number of the remedies available for use as specifics, as the result of increased knowledge of the phenomena of cell life on the one hand, and the action of remedies on the other.

Thus far the field for specific treatment has been confined to diseases in which a foreign morbific element has been introduced into the system, with the exception of myxedema and its kindred diseases, in which the source of trouble is the absence of something furnished by the thyroid gland which is necessary to a proper action of the economy. Here the artificial supply of thyroid gland or its extract constitutes an efficient specific treatment. In diseases having a parasitic origin the problem is to act upon the specific microorganism in such a way as to prevent a further production of toxin. What is aimed at is not destruction of the germ, but inhibition of its activity. Different strengths of solutions of the same agent may represent two classes known as germicides (or disinfectants) and antiseptics. Thus, mercuric chloride in a strength of 1-300,000 will prevent the development of anthrax spores, while destruction of the spores requires a strength of 1-1000. A further difference in favor of antisepsis within the body, as distinguished from that observed in the laboratory, arises from the fact that blood-serum, so long as it is circulating in the vessels of a living animal, acts by virtue of its vital condition as an antagonist to bacterial growth. An assumption that is exceedingly common is that for combating germs within the body one must look to those agents that are relied upon for use as disinfectants outside the body; and it is claimed that safety in the use of this requires such a degree of

attenuation as would make them inoperative. It is a fact, however, that not one of the recognized specifics would be employed outside the body for its disinfectant properties; and, furthermore, quantities of the appropriate agent amply sufficient for the purpose are constantly being given as specifics with entire safety. The case for specific medication outside the few diseases for which it is universally admitted to be indicated, it may well be believed, is not so hopeless as is commonly supposed. It is not necessary that there should be only one specific for each disease, as is shown particularly in the instance of malarial fever, which may be successfully treated not only with quinine, but also with arsenic, salicin, carbolic acid, ammonium picrate, and perhaps some other remedies. To say that there is no specific for pneumonia, because so many different agents will inhibit the germ upon which it depends, is to argue that a thing cannot be done because there are so many ways of doing it. The criticism has been made that the effect of different antiseptics and germicides upon parasitic micro-organisms must bear a definite relation to the mass of blood in which they are diluted, which may be roughly estimated as 12 to 14 pints in the adult; but what definite relation does half a dram of quinine or of potassium iodide, or two or three drams of a salicylate, or a dose of antitoxin bear to 12 or 14 pints of blood? Who asks such a question in the presence of a case of malarial fever, of syphilis, of acute rheumatism, or of diphtheria?

In pneumonia the conditions are very favorable for acting directly upon the germs, so that theoretically the *a priori* aspect of the case is encouraging; while from the clinical side accumulating experience seems in a considerable measure to support the theoretical deductions. Of the drugs which appear to act more or less specifically in this disease, the one which thus far seems to have accomplished the most is the salicylate of sodium. One notable feature of its use is that lysis is substituted for crisis as the habitual mode of defervescence, the lysis, when the treatment is begun early, occurring in advance of the usual time of crisis. Beginning with the report of Liegel's cases in 1898, the writer gave a résumé of the results thus far obtained with this agent. He then went on to say that he had found the carbonate of creosote, also believed to control the action of the pneumococcus, nearly as efficient. It can be given in quantities of two or three drams a day without the slightest inconvenience, and will usually bring about a lysis commencing twenty-four hours after the administration is begun. It is to be preferred when the stomach is inclined to be irritable, and also in cases of considerable depression when the sweating caused by the salicylate would be objectionable. In a series of 20 cases recently treated with this remedy at the New York Presbyterian Hospital (after excluding those already moribund and those complicated with conditions necessarily fatal in the presence of any severe acute disease) two died, a mortality of 10 per cent. chargeable to the pneumonia. In the *Medical Record* of February 1, 1902, Dr. W. H. Thomson published the details of 18 cases treated with creosote carbonate with one death.

In the remainder of the paper Dr. Smith spoke of the specific treatment of influenza, scarlet fever, gonococcic infection, gout, and rheumatism. He referred particularly to the success obtained by Dr. S. H. Dessau with carbolic acid in influenza and to the remarkable results with the same remedy in scarlet fever reported by Wigglesworth, of Liverpool. In conclusion he said that while the bacteriologist is at work in his laboratory, the clinician on his side has a field for action. Carefully-conducted experiments will show that the present dosage of remedies may be safely exceeded in some cases, or that objectionable effects may be avoided by combinations of remedies which yet will leave the specific action intact.

Creosote Carbonate in Pneumonia.—Dr. L. F. Bishop spoke of his experience with the use of creosote carbonate in pneumonia in the Colored Hospital, and said that on the whole he had been very favorably impressed with it. In a number of cases there were existing conditions which rendered them practically hopeless. Of five uncomplicated cases three recovered and two died. In spite of this comparatively large percentage of mortality, it seemed to him that the remedy was of essential service. He had recently seen a case in which it acted very happily. Lysis had occurred and the patient recovered in a very satisfactory manner.

What is Meant by a Specific?—Dr. James K. Crook quoted the definition of the word specific as given by various authorities, and said that if one accepted these one would be obliged to exclude from the category of specifics several of the most important remedies referred to by Dr. Smith. Specifics other than drugs were sometimes mentioned. Thus, climate was spoken of as a specific for phthisis, a sea-voyage as a specific for dyspepsia. Again, methods of treatment were called specifics, as hydrotherapy for rheumatism and homeopathy for whooping-cough and tonsillitis. For his own part he thought there was very little use for this term in modern medicine. Most of the specific systems of treatment, as well as many of the much-vaunted "specific" drugs of the past, had sunk into merited oblivion. That most virile of latter-day specific cults, homeopathy, was also gradually passing away, and he gave some statistics showing its decline. At the present time a number of remedies, such, for instance, as sodium salicylate and creosote carbonate, were looked upon as specifics; but it was a question whether they might not in the coming years be regarded in the same light as so many of the so-called specifics of the past. As an illustration he referred to the history of potassium chlorate. Hope for the future lay in rational therapeutics, and it should be the aim to use remedies for certain definite purposes which they were known to accomplish. Nitroglycerin, for instance, was known to cause dilatation of the blood-vessels, and it could always be depended upon to fulfil that indication. This kind of therapy could not be overthrown.

The Treatment of Pneumonia.—Dr. Egbert Le Fevre said that, while he had used both the salicylate of sodium and the carbonate of creosote, he had to confess that he felt some hesitancy in pushing these remedies to the full limit advised by some writers. The temperature fell by lysis and a fair proportion of the patients recovered, and yet he could not but think that for the most part they would have done quite as well without such treatment. He was, therefore, still in doubt as to its efficacy, and it seemed to him that there was some danger in putting these remedies forward as specifics.

The Use of Creosote.—Dr. Beverley Robinson said he was sorry to differ from the writer on many of the points that he had advanced. As to creosote, he believed it to be about the best anticatarrhal agent we possessed. It also had perhaps a certain amount of antiseptic quality. The best way of getting it into the system was by means of inhalation. In bronchitis or threatened bronchopneumonia and in commencing croupous pneumonia it was his practice to employ vaporized creosote in the room. In this form it was also the best protective agent for all those who had to be in the sick-room. He did not believe that there could be a specific for pneumonia, because the cases differed so greatly in character.

Preventive Medicine.—Dr. R. E. Van Giesen said that in therapeutics the tendency at the present day was toward prevention. He thought it most unfortunate that the announcement of Koch's tuberculin had been made to the world prematurely. With the improvements that had been made in its employment he believed that it would be generally recognized as having a distinct field of usefulness. He felt convinced, however, that it would never be of benefit except in the early stages of tuberculosis.

Serumtherapy.—It seemed to be a fact that every microbe has the capacity of developing its own antitoxin. Personally, he had looked upon the advent of diphtheria antitoxin with suspicion, but after he had made an investigation of the matter himself he felt convinced that as far as diphtheria was concerned a specific was in sight. The antitoxin should be employed at the earliest possible moment, for the later in the disease it was given the smaller was the chance of its proving successful. He believed also that other infectious diseases would give up their germ and would be benefited and conquered in the same way as diphtheria.

Dr. Homer Wakefield called attention to the fact that in rheumatism the salicylates, when given between meals, did not seem to have the same effect as when given at or immediately before or after meals. The bacterial product of fermentation might be either gastric or intestinal, or both, and when the fermentation was more intestinal than gastric salol acted more efficiently than the salicylates. In pneumonia, again, creosote acted better when given with meals than on an empty stomach.

Carbolic Acid in Influenza.—Dr. S. H. Dessau said that for the past six years he had employed carbolic acid constantly and freely, on the ground of its supposed action as an internal antiseptic. He had given it to thousands of children and had never met with an accident from it. He had found it especially useful in cases of modified influenza with subacute bronchitis when there was a persistent irritative cough. He had also employed it with success in typical cases of influenza.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, Held February 13, 1902.

The Chairman, Rowland G. Freeman, M.D., in the Chair.

Acquired Syphilis in Child.—Dr. Sara Welt Kakels presented a girl, eight years of age, suffering from acquired syphilis. The initial lesion had been on the clitoris and the child had had the usual secondary symptoms. The general adenopathy was quite marked and the lymph-nodes in the groins were especially enlarged. The enlargement was the characteristic discrete nodular hyperplasia that occurs in acquired syphilis.

Specific Stomatitis.—Dr. Henry Heimann presented a child suffering from stomatitis thought to be due to specific forms of micro-organisms. Scrapings from the stomatitic patches showed the presence of the bacillus of Vincent and the spirillum of Miller. The affection has been noted in a large number of cases, always associated with these two micro-organisms and thought to be due to their action. The treatment is by the use of silver solution in a strength of five to ten per cent. It occurs in run-down children and may prove enduring unless properly treated early.

Adenoid and Tonsil Pathology.—Dr. A. J. Lartigau said that the physiology of the normal tonsil is not very well understood as yet and physiologists are not very definitely agreed as to all of its functions. The lymphatic tissue of Waldeyer's ring can be best studied in the faucial tonsil. Its lymphatic structure corresponds very closely to that of Peyer's patches, but there is no agreement as to the interpretation of its functions here. There is no doubt that substances can be absorbed through these lymphatic patches and such powders as carmine, soot and cinnabar have been demonstrated at some distance from the surface after having been placed on the surface of the normal lymphatic tissue. Goodale considered that these powders are normally absorbed, partly through the lacunæ of the tonsillar tissue, and that they partly follow the connective tissue layers, while some of the grains are carried by leucocytes. Undoubtedly the absorption of bacteria with the pathological changes they induce opens the way for the absorption of other substances. It has been thought that absorption would not take place through the normal mucous membrane, but the present trend of opinion is against this notion. The leucocytes in the tonsillar tissue are not true phagocytes, as a rule, although some of them are. The lymphatic tissue in the tonsillar region is not smooth in outline and is not covered by ciliated epithelium, hence there is a lack of protection. There is a great liability to mechanical lesions owing to the swallowing of imperfectly chewed food. The irregularity of contour of the tonsils and the presence of crypts furnish special lurking-places for irritant particles, bacteria and other offending material. Saliva is thought to have a positive chemotactic action. The lymphoid tissue in this region furnishes protection against bacterial invasion, first, by its filtration action, secondly, because it attenuates the virulence of bacteria present, and, third, because there is a tendency to immunity from the free cells that exist in the parts.

Tonsillitis Varieties.— There are many varieties of tonsillitis, although they are apt to be grouped together in the practitioner's mind. Some of the pathological processes here are deep, some are superficial, some are exudative, and some are hyperplastic. Many of them are due to micro-organisms, the most common invaders being the various pyogenic micro-organisms, especially the streptococcus and staphylococcus, and after these the diphtheria bacillus, the pneumococcus and the bacillus tetragenus. Syphilitic infection of the pharyngeal tonsils has not been reported, although syphilitic affections of the faucial tonsils are not rare. Primary, secondary and tertiary lesions may occur. The diplococcus lanceolatus is a frequent cause of tonsillitis. In eleven cases of non-diphtheritic tonsillitis cultures taken from the throat proved to be sterile in five cases, while in six the growth showed a mixed infection consisting mainly of the streptococcus, but in a form that is rather non-virulent for rabbits.

Tuberculosis of Tonsils.—The results of the gathering of statistics with regard to tuberculous affections of the tonsils are somewhat discordant. The disease may be either primary or secondary. Secondary tuberculous tonsillitis occurs in chronic pulmonary tuberculous patients. This is not uncommon. About 80 per cent. of consumptive patients suffer from it. In 21 cases examined by Strassmann 13 showed tuberculous tonsillar lesions. In Schlesinger's cases every one had an affection of the tonsils. Primary tuberculosis of the tonsils is rather rare. Eighty cases examined for the purpose showed not a single positive result. Tuberculosis of the tonsils, when primary, is focal in character, small in area, and is situated near the surface of the tonsils. Pharyngeal tuberculosis, being localized in character, is often missed and treatment would probably be of little avail considering the condition of the patient.

Surgery of Adenoids.—Dr. W. K. Simpson said that some practitioners still think that there is no need to remove adenoids. They wait for Nature to relieve the condition that exists or fondly deceive themselves with the idea that the patients will outgrow it. The effects of adenoids are more deleterious the longer they are allowed to remain. These effects are seen in many parts of the body. Many cases of spasmodic croup are really due to the nervous reflexes induced by the presence of adenoids. The obstructed voice, the middle-ear deafness and the suppurative otitis media, so often seen in children, are usually due to adenoid enlargements. The mouth-breathers suffer from disturbed sleep, from malformations of the chest, from mental listlessness, and from general disturbance of normal development. If at the same time hypertropied tonsils be present, this makes the condition worse and the little patients are liable to constantly recurring attacks of pharyngeal and laryngeal inflammation. The only treatment that is of any real service is the radical removal of the overgrown tissue. Careful digital examination should be made in order to decide just where the adenoid masses are, so as to be able to remove them. Removal should be accomplished by instruments. The finger only serves to break up the masses and portions of them come away piecemeal, but the tumors are not detached from their bases. After the forceps are employed, the finger should be again introduced in order to ascertain whether other portions are removable. The curette serves a useful purpose in taking away shreds. For the removal of adenoids the Wilds snare is a very difficult instrument to employ, especially in children in whom there is very little room for its manipulation, and at best it should be reversed for young adults. Whether the curette or the forceps should be employed is a matter of individual practice. As a rule, there is less shock after the operation if no anesthetic is employed and the patients lose less blood. It is possible that under anesthesia portions of the adenoid growths may find their way into the larynx. One of the faults with the old forceps for adenoid operations was that the cutting surface was too small. The instrument took away only a very meager portion of the growth and it was difficult to reach a definite point in the nasopharynx to remove the vegetation. Modern forceps are, however, made with a much larger bite and with a sheath covering that saves the uvula from any chance of injury and protects the soft palate. As a rule, a much larger instrument can be employed even in small children than might be imagined. A child of three or four years of age will not be inconvenienced much by the largest forceps. The child should be put on a table on an inclined plane in order that the blood may readily make its escape. The curette to be employed must be more curved for adenoids that exist in the vault of the pharynx than for those on the posterior wall. When adenoids project more or less into the posterior nares the palate should be brought forward with a finger or the retractor to facilitate their removal. By the exercise of proper care practically all of the growth can be removed. Careful preliminary examination is the most important part of the technic for it enables the surgeon to decide just how his instruments must be applied.

Recurrence of Adenoids.—At times after the patient's upper respiratory passages have been free for some time following an operation they again become blocked up and an apparent recurrence takes place. This is evidently due to an inflammatory overgrowth of portions of the adenoid tissue which have been left behind. It is often impossible completely to remove adenoids. They exist at times at the sides of the nasopharynx or even in the fossæ of Rosemueller. At times, too, the growths project into the posterior nares and it is almost impossible to secure their complete removal. The portions left seem to take on renewed development and this constitutes the apparent recurrence. As a rule, the fork in the tonsillotome should be without darts. The darts add very little to the value of the instrument and they sometimes add considerable to the inconvenience of its application. There are three requirements for tonsillotomy: First, the tonsils should be well engaged; second, as small an amount as possible should be left behind, and, third, the pressure upon the tonsil from the outside should be kept up. After the operation nothing should be seen between the pillars of the fauces. Dr. Simpson considers the Mackenzie tonsillotome an ideal instrument. It serves very well as a mouth-gag and can do no harm. At times the tonsil is adherent to the pillars of the fauces. It may be separated by means of a bistoury or hooked tonsil knife. The flat broad tonsils that cannot be encircled by the tonsillotome may be operated upon by means of the punch forceps, which do their work very well, or may be reduced in size by means of electropuncture. This last process is, however, very slow.

Hemorrhage and After-Treatment.—In operations upon children's tonsils there is very little danger of hemorrhage. Few serious cases have been reported and almost without exception these have not been fatal. Secondary hemorrhage is said to occur a little more frequently after the employment of adrenalin to prevent primary hemorrhage. This is not, however, sure and more experience will probably serve to show that it is rather an undergrounded fear than a real danger. When an artery spouts torsion forceps should be applied. If the bleeding be a general oozing instead of from any definite point, the perchloride of iron should be used in order to stop it. As a rule, no after-treatment is required subsequent to tonsillotomy. Douching and insufflation of powders should be forbidden. Cracked ice may be allowed for twenty-four hours afterward and seems to add to the comfort of the patient, while it lessons the risk of hemorrhage. The patient should be advised to sleep with the head rather high, and rest during the day succeeding the operation should be insisted on. Little children should not be allowed to play about the room, and the eating of hard morsels as bread crusts or even meats should be forbidden. Liquid foods should be prescribed. As a rule adenoids can be removed with less hemorrhage without an anesthetic. There are, however, extremely nervous children for whom an anesthetic may be required.

The Lymphatic Constitution.—Dr. James Ewing said that it has now come to be recognized that sudden death occurs rather frequently in certain cases in which no definite organic lesion to account for it can be ascertained. In these cases there is often found on autopsy a general lymphatic hyperplasia that involves all the lymphoid tissues of the body. Not only are the lymphatic nodes enlarged, but there is usually enlargement of the various structures of Waldeyer's ring, of the pharyngeal tonsils and of the lymphoid structures of the intestines, Peyer's patches, etc. Accompanying this lymphatic condition there is a hypoplasia of the aorta and a failure to develop of certain other organs. The most interesting hypothesis recently suggested with regard to the lymphatic constitution is that of Ohlmacher, who believes that most epileptics suffer from the condition and that fatal epilepsy is especially apt to be associated with lymphatic enlargements in various portions of the body. Typical *grand mal*, he thinks, always has the lymphatic constitution for its basis. Nervous symptoms are frequently associated with the lymphatic constitution and this subject is developing in

a manner that is of great practical interest. The neurosis of Basedow's disease and the enlarged thyroid are perhaps associated with this lymphatic constitution.

Recent Anatomical Advances.—Dr. William Elser showed by observations made in the laboratory of the Cornell Medical School that hemolymphatic nodes are frequent in the bodies of patients dead from the status lymphaticus. Quite recently attention has been directed to the atrophic stage of the disease. In these cases with the associated lymphatic enlargements there are infantilism of the sexual organs, the open foramen ovale of the heart and a small pelvis. At times it has been thought that the sudden death in the status lymphaticus was due to cerebral anemia, but this is doubtful. It has been pointed out that a catarrhal inflammation of the mucous membrane exists about the enlarged lymph-nodes, and it is thought that the latter predispose to enteritis and at times perhaps also to tuberculosis.

Thymic Asthma.—The impression has been gaining ground in recent years that the symptoms ordinarily called "thymic asthma" always develop on a basis of the lymphatic diathesis to which are subsequently added the other symptoms of the asthmatic condition. There is now no doubt that the enlarged thymus does sometimes cause sudden death by its pressure upon the trachea and upon important nerves leading to the larynx. In one case the patient has been saved by cutting down upon the enlarged thymus and sewing it to the sternum. The sudden death in these cases is due to capillary bronchitis only in rarer instances and the symptoms are of slow development. The general nervous condition is now thought to be more important than anything else in the etiology of the symptoms of the condition. The hypothesis that they were due to hyperthymization of the system has not been confirmed. It is true that the injection of extract of the thymus causes dyspnea and other symptoms in young animals and seems to lower their resistive vitality. This does not of itself, however, prove the theory. It is probable that the further study of the sympathetic nervous system may lead to some important developments with regard to the pathogenesis of the lymphatic constitution. When the status lymphaticus exists the administration of chloroform is nearly always fatal. The question at issue is, is chloroform ever fatal in any cases except those associated with the status lymphaticus? At Gratz all the fatal cases of chloroform narcosis in children have been found to be associated with the lymphatic constitution. The diagnosis of the lymphatic constitution is not impossible. The existence of the enlarged lymph-nodes throughout the body can very easily be recognized. If to this general adenopathy there is joined an enlargement of the visible lymph-structures at the back of the throat, especially the tonsils and adenoid tissues in the nasopharynx, it would seem almost unjustifiable to use chloroform as an anesthetic. This is an extremely important practical question to which sufficient attention has not been given. [Dr. Ewing's paper will appear in a subsequent issue of the Medical News.]

Treatment of Cervical Lymph-Nodes.—Dr. Charles N. Dowd said that it is extremely common to find the lymph-nodes of the neck enlarged as the result of sore throat. Single nodes may develop to the size of a horse-chestnut and yet subside without breaking down. They may last for months and yet disappear by resolution. The main question of interest in all cases is, Are they simple inflammatory enlargements or are they due to tuberculosis? As a rule, simple inflammatory enlargements reach the size of hickory-nuts, cause stiff neck for some days and then subside. In a recent case, however, Dr. Dowd has seen intense dyspnea develop as the result of the breaking-down of a series of inflamed lymph-nodes and this was only relieved when pus was evacuated from the deeper structures of the neck. Dr. Dowd has had some recent cases in which it was extremely difficult to decide what was the etiology of the condition. It was also very difficult to decide whether surgical intervention should be undertaken or not. In one case the temperature ran up to 104° F., and then had a series of remissions, but always with high temperatures in the afternoon. Dr. Dowd felt sure that pus was present and yet the enlarged lymph-nodes subsided without operation. Dr. Dowd exhibited a patient who had suffered from eczema of the face and then developed a swelling nearly as large as a pullet's egg beneath the jaw. This is rather hard in consistence, does not give pain and is not tender. The question is, Is it tuberculous in origin and will it suppurate? Most tuberculous enlargements may last for several years and yet remain rather small. As soon as it is definitely decided that the enlargement of the lymph-nodes is due to tuberculosis, they should be removed. The resulting scars are less in this case than if abscess formation and spontaneous evacuation were permitted. As the result of operative treatment for this condition in Berlin, 70 per cent. of cures are reported while only 24 per cent. were cured by expectant treatment.

Conservatism as Regards Adenoids.—Dr. Jacobi said that if adenoids be very large in children, they should be removed. Surgical intervention is not needed, however, for small adenoids, even though they produce such symptoms as snoring and mouth-breathing. In these cases parents should instruct their children to irrigate the nares with warm salt water or boric-acid solution. This irrigation should be done very slowly; injections under pressure must by no means be made. Dr. Jacobi has seen many hundreds of cases in which symptoms were relieved by this simple means and no operation was needed. Adenoids should never be removed under general anesthesia, because in order to relax the spasm of the masseter muscle, one of the strongest in the body, the child must be anesthetized within an inch of its life. It is easy to remove adenoids by having the mother sit down in front of the doctor and hold the child on her knee, allowing its head to drop between the knees of the doctor. The little patient is thus held firmly, the blood finds its way out through the nose and the operation is over in a few minutes.

Dr. Quinlan deprecated the use of irrigation as tending to lessen the good that might be accomplished by the radical removal of adenoids. The results of the condition are too serious to allow temporization; when adenoids exist they should be removed.

Dr. Dowd said that since the administration of chloroform is liable to be fatal in children suffering from adenoids it should not be used. Dr. Lartigau said that ether also causes death when the lymphatic constitution is present. Dr. Jacobi said that chloroform is preferable to ether for child narcosis, because it kills through the heart and the child's heart is proportionately stronger than that of the adult.

SPECIAL ARTICLES.

THE MEDICAL DEPARTMENT OF TULANE UNIVERSITY OF LOUISIANA.

THE founding and upholding of the Medical Department of Tulane University of New Orleans was largely due during its earlier years to the energy of two young men who were born far away from one another, educated under totally different conditions, and who met and formed a friendship under the most tragic and harrowing circumstances.

The names of Thomas Hunt and Warren Stone are among the greatest names of New Orleans and in the annals of the Medical College. Both were born in the same year, 1808, but, while Dr. Hunt's family were wealthy people who had come from the West Indies, Dr. Stone was the son of a Vermont farmer. Dr. Hunt was born in Charleston and brought up with every advantage that wealth and education could give to a remarkably precocious and clever boy. The classics, law and literature were his accomplishments before he selected medicine as his profession. He took his degree at the University of Pennsylvania at the age of twenty-one and went to Paris for a year and a half, returning to Charleston on the death of his father.

While he was receiving the education and the introductions that were to insure him a reception in the best families and in the highest medical circles of the South, his unknown contemporary, a fatherless boy in St. Albans, Vermont, was getting the scanty education of a farmer's son in New England. His mother, however, supplemented the deficiencies and aided him materially in the preparation for the study of medicine. After graduating from the Medical School of Pittsfield, Mass., in 1831, he began to practise in Troy, N. Y., and it so happened that he was called upon to attend the first cholera case that was brought to Troy, which came with the emigrants to Quebec and Montreal, who, in their alarm, fled to the States by way of Lake Champlain. Dr. Stone promptly recognized the new disease and attended the destitute victim. Thirty-five years later he wrote a paper on cholera and its treatment, in which he said: "It so happened that my professional life and the cholera in this country commenced together," and it is a wonder that his professional career did not end when it began, with the cholera; for his experience in Troy was but the introduction to the exciting siege with it in the cholera ship "Amelia," in which he embarked for New Orleans, where he had determined to settle and practise.

The brig "Amelia" left New York with 108 passengers. Four days out a terrible storm came on and all the passengers, four of whom had started from New York with cholera, were stifled under the hatches, which were closed to keep the ship from sinking. When the storm passed Dr. Stone found twenty-five persons in the second stage of cholera. The vessel was beached on Folly Island, off Charleston, and was soon boarded by wreckers who carried the disease with them from the ship. The island was the property of a planter, Mr. Alexander Milne, who opened his house to the sick and destitute shipwrecked people and generously furnished supplies. The wreckers were forbidden the ship and it was burned. All communication with the mainland was cut off, except for the physicians who were sent out by the city. Three were in turn sent to quarantine the island and tend the sick, but returned exhausted. Then young Dr. Hunt was appointed and given full charge. A few months before he had prepared such a complete and extensive memoir on the subject of cholera and the measures for its prevention that it was afterward published for practical use when the disease spread. He entered on his task with great courage and energy. The passengers and negroes of the plantation demanded his incessant personal care, but in the midst of the strain and horror he was assisted at every turn by Dr. Stone. These two youths of twenty-three bore the brunt of the work together and formed a friendship which endured through their lives.

Sickness was the reward of Dr. Hunt's efforts and poverty the result of Dr. Stone's journey. Both were thinking of New Orleans as a place to settle and discussed their future together. On leaving Folly Island Dr. Hunt returned to Charleston, where he was received as a hero and where he was presented by the citizens with a massive silver goblet as a testimonial of their gratitude, while Dr. Stone continued his journey to New Orleans, and in December, 1833, arrived on the levee with one picayune in his pocket. He often said, half humorously, that he would not have saved this, but for the sake of preserving a nucleus.

It was in that year that cholera claimed six thousand victims from a population of fifty thousand, and that in a city where yellow fever was also epidemic. The ravages of the two frightful pestilences filled the new Charity Hospital to overflowing and, through the kindness of Dr. Cenas, Dr. Stone was appointed to a position in this hospital.

A few months later Dr. Hunt, who had moved to New Orleans and succeeded Dr. J. M. N. Picton as house surgeon, renewed his friendship with his companion of the Folly Island pestilence, and through his recommendation Dr. Stone became assistant house surgeon under Dr.

John H. Harrison, house surgeon, upon the resignation of Dr. Hunt, who had conceived the plan of using his energies in founding a medical college in New Orleans.

The name of Dr. Harrison introduces another brilliant young man to the trio of future great men of the city and of the yet unfounded medical school. John Harrison was also born in 1808, but in Washington. He came of an old and well-known Maryland family, and inherited his taste for medicine from his father, who was a surgeon. He studied medicine with his uncle, Dr. Baltzell, and was graduated from the University of Maryland in 1831. His classical and scientific education had been excellent and he was proficient in foreign languages, so that when he came to New Orleans to begin the practice of medicine as a mere boy he was thought rather a poetic and philosophic young fellow, and he had no very extensive practice at first.

Dr. Hunt's ambition to awaken New Orleans to its opportunity of becoming a medical and scientific center gave Dr. Harrison the opportunity just mentioned to enter the Charity Hospital; so the three forceful and able youths were brought into close and practical relations.

The condition of medical education in the United States was at that time in need of improvement. "The great majority of its physicians had no better medical education than that gained as pupils in a doctor's office, and American medical colleges originated as substitutes for this very inadequate apprentice system. Colleges were neither founded, nor financially aided, nor supervised by a paternal government, as were most European colleges, but were the offspring of private enterprises. In fact, almost every one was a joint stock company, composed of a few ambitious medical graduates. The maintenance of these colleges, including the salaries of the self-appointed professors, was wholly dependent on the number of students and the amount of their fees. Hence, the colleges were forced, in order to survive, to adopt such measures as would tend to increase the number of students."

The Medical College of Louisiana, which was the germ of Tulane University, was just such a joint stock company and was the outcome of Dr. Hunt's enthusiasm and energy. He delivered the introductory lecture in September, 1834, and was appointed professor of anatomy and physiology and elected dean. His associates were Dr. Charles A. Luzenburg, Dr. J. M. Mackie, Dr. T. R. Ingalls, Dr. A. H. Cenas, Dr. E. B Smith, and Dr. Warren Stone, who was given the demonstratorship of anatomy in the place of Dr Harrison, who was deterred from serving on account of ill-health.

In the first session eleven students were graduated, but the numbers increased through the persistency and the excellence of the faculty. The requirements, however, were not very great. Attendance at two annual sessions of four months each was required, and, as students could enter very late and leave very early, there were instances of cases in which little more was required than one's presence, payment of the entrance fees, and attendance at the final examinations; so the early standard of the college was no higher than that of its contemporaries. Although a third year of practical experience in a doctor's office was formally required, certificates of such study were frequently worthless.

Dr. Chaillé, of the class of 1853, says of the regulations at that day: "I myself was graduated in 1853, only seventeen months after opening a medical book for the first time, and, to prove how very little was then required, I was graduated, as were no doubt many others, by the unanimous vote and with the congratulations of the faculty, and no question was ever asked as to how long I had been a student of medicine."

Until 1868 every candidate was examined by every professor on the same day, one professor following another, and each occupied so little time that in about an hour and a half all the examinations to which any one student was ever subjected were completed. These hasty examinations were exclusively oral and were never preceded by any reports from laboratories or any other source, as to the amount and efficiency of any work done by the student. Brief as was the examination of every professor, part of his time was often devoted to kind inquiries as to the welfare of the student and his family.

From 1834 to 1867 the Medical College of Louisiana never had more than eight or ten teachers, instructing in only eight or nine branches of medicine and in only two laboratories; but the men whose names appeared on the first faculty, as well as others who for many years worked together, gave an impetus to the study of medicine that the mere routine work of text-books and laboratories often lacks; and no better reminiscence of the early days of the Medical School can be given than by recalling the personal characteristics and the life-work of Dr. Hunt, Dr. Stone and Dr. Harrison, as well as their distinguished associates.

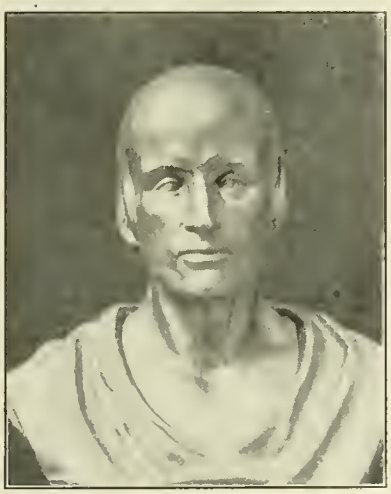
Dr. Harrison, not finding the hospital work wholly to his taste, gladly accepted the chair of physiology and pathology in the Medical School and resigned from the hospital in favor of his powerful young assistant, Warren Stone; he became attending physician, while he threw his whole energy into physiology. In a few years he had read, translated, examined, and experimented with every branch of science connected with the subject of physiology, and had prepared a course of lectures that attracted the better class of students. So elaborate in scientific and philosophical detail were these lectures that it required an ample preliminary education to understand them, but that very requisite raised the standard of the students' ambitions, and Harrison's reputation and popularity drew many men to the college.

In 1844 Dr. Harrison published in Philadelphia a valuable book, "The Nervous System,"

and in 1845 he became one of the four editors of the *New Orleans Medical and Surgical Journal,* founded in 1844. He was in the prime of his professional activity and at the center of the advanced medical work of the South when he was taken ill and, in spite of travel and rest, died in 1849 at the age of forty years.

Dr. Harrison was small and refined, while Dr. Warren Stone was a huge, rugged man. The latter's unusual height and weight were intensified by his massive head and by the imposing strength of his features, which, though not handsome, were striking and impressive. He, the giant, and Dr. Harrison, the diminutive man, were the best of friends, differing from each other only in size.

Dr. Stone filled the position of demonstrator, lecturer and professor of anatomy during the first few years of the College's existence, and in 1839 was made professor of surgery, which chair



J. H. HARRISON, M.D.

WARREN STONE, M.D.

he held until the year of his death, 1872. From Dr. Charles J. Bickham, Dr. Stone's ward student in 1855 and 1856, we get the flavor of personal reminiscence concerning his hospital work. "He was methodical and industrious, quick in perception, prompt in the execution of what he perceived to be his duty. His resources were unbounded. He never seemed to be taken unawares. His knowledge, tact and ingenuity were equal to the occasion and he never appeared so cool, self-possessed and grand in his whole nature, physical, mental and moral, as in the midst of alarming emergencies in surgery. In the midst of the most complicated and difficult operations, cool, calm and collected, he would promptly do his duty, at the same time lecturing and explaining to those present the minutest practical details of the case. In truth, every visit to the hospital was an ovation to him, which he acknowledged with becoming modesty, but which served doubly to inspire him. In his surgical clinics he taught the principles of drainage in suppurative arthritis, in hepatic abscess, and in pyothorax. In the surgery of arteries he was an expert and was among the first to cure aneurism of the vertebral artery. In November, 1849, he operated successfully on a case of traumatic aneurism of the vertebral by incising the sac, turning out the coagulum, and controlling the artery by a graduated compress. For fourteen years at the Charity Hospital he operated without an anesthetic; but, although the *New Orleans Journal,* as well as others in the country, decried the use of ether, with its toxic powers and its patent, Dr. Stone welcomed it and showed his independence in February 25, 1847, by amputating the thigh of a man under ether. When chloroform was introduced, however, it became his favorite anesthetic and it is largely due to his professional teaching that it is the preferred anesthetic of Southern practitioners.

The Maison de Santé, one of the earliest private hospitals in America, was founded by Dr. Stone in connection with Dr. Wm. E. Kennedy in 1839 and twenty years later became Stone's Infirmary, where he continued his extensive work in general surgery Although it was a private hospital, it was the established rule of the house never to refuse professional services on the score of poverty, and the charity dispensed by Dr. Stone at the Maison de Santé, according to one of his colleagues, "was of itself sufficient to elevate its author to that high rank among philanthropists which his well-known abilities had long since commanded in his profession."

As consulting surgeon to the Hôtel Dieu, Dr. Stone served for twenty-three years. The most important part of his professional life and work, was, however, his connection with the Medical Department of the University of Louisiana, which he served for thirty-eight years, from January, 1835, to April, 1872, when he resigned. As a teacher of surgery he was discursive rather than systematic, but though he was apt to be

led off the beaten track by an interesting case in hand his lectures were always instructive and convincing, especially to graduates.

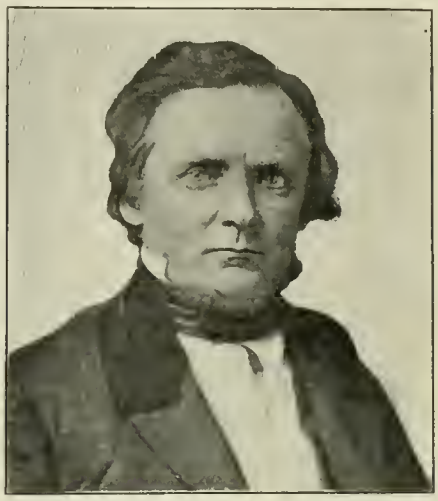
Dr. Stone was not as well known by his writings as by his works, being reluctant about expressing himself in print. All the more important contributions that he made were published in the *New Orleans Medical and Surgical Journal,* and were pithy and convincing; but it was as a man, noted far and wide for his great wit and wisdom, and in his relation to the individual patient that he was so widely and affectionately known. Professor Samuel D. Gross once called him "The Great Commoner of Medicine," and so great was his name in his city and so deep was the love of the people of New Orleans for him that, when he died, December 5, 1872, the District Courts were adjourned as a mark of respect, the flags of the shipping stood at half-mast, and many of the stores on the main streets were closed at the time of the funeral.

Dr. Hunt, to whom the growth of the Medical College was his greatest interest, threw himself into the work of placing it on a solid foundation as a permanent State institution, giving up much of his large practice for that purpose. In 1845 he accomplished his end. When the new constitution for the State was adopted a clause was put into it establishing a State University and constituting the "Medical College of Louisiana" as then established as the Medical Department of the University. In 1847 Louisiana permitted the medical faculty to erect the first building it ever owned on a lot belonging to the State, on

THOMAS HUNT, M.D.

two conditions: First, that the members of the faculty should give their services to the Charity Hospital without pay, instead of being paid therefor, as had previously been the case; and, second, that one beneficiary student from every parish should be admitted annually for the next ten years; and this was extended in 1853 to ten years more. The first condition has always been fulfilled and the second condition was fulfilled for at least twenty years. The number of students increased from thirty-eight in 1843 to one hundred in 1846.

In 1844 a large amphitheater for surgical operations and for lectures was erected in the Charity Hospital at an expense of $5,000, half of



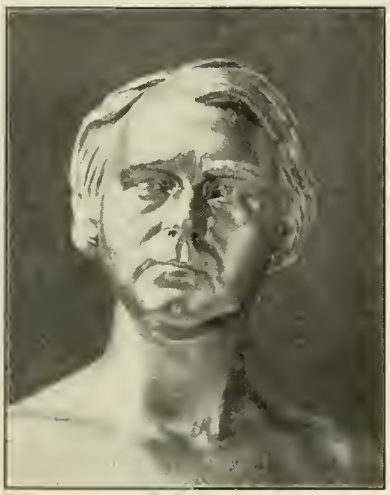
JOHN LEONARD RIDDELL, M.D.

which was contributed by the faculty. Various endowments and grants, besides the use of the lot and buildings, had contributed by 1859 about $83,500; the number of students had increased from 100 in 1846 to 276 in 1858, and this increase would have been greater but for the fact that during these eleven years there occurred five of the worst epidemics of yellow fever that ever desolated New Orleans. In 1863 the Medical School had matriculated 4,119 students and had at the session of 1860-1 over 400 students. But when New Orleans was captured in 1862 by the United States Navy and Army, the Medical Department was obliged to suspend until the session of 1865-6.

Dr. Hunt, whose fortunes were shattered and whose health was feeble, left New Orleans for a time and went to Havana, where his reputation brought him a large practice, despite the fact that at fifty-four years of age he was obliged to learn a new language, and where he received a degree in the name of the Royal University of Havana.

In 1865 the Medical Department reopened its doors. The building had been occupied by the United States military and one wing used for a colored school in charge of the Freedman's Bureau was terribly dilapidated; the library and apparatus were damaged and the treasury was empty. But on his return from Havana Dr. Hunt interested himself in obtaining from the Legislature of 1866 a new appropriation of $25,000 for the immediate needs of the College, and devoted himself to repairing the fortunes of the institution. The students came back, the faculty

was reorganized, but Dr. Hunt's efforts were terminated by his death March 20, 1867. The Medical College lost one who had been a man who had unselfishly devoted his energies to the practical advancement of medical science. He was an attractive lecturer; but his fame as an orator is only traditional as he published little.



A. C. LUZENBERG, M.D.

and the address which he delivered on "The Utility of Science," when he became dean, was one of the few that were printed.

Those who were chiefly instrumental in founding and in maintaining the college were Drs. Hunt, Luzenburg, Cenas, Harrison and Stone, aided as early as 1836 by Drs. James Jones and J. L. Riddell.

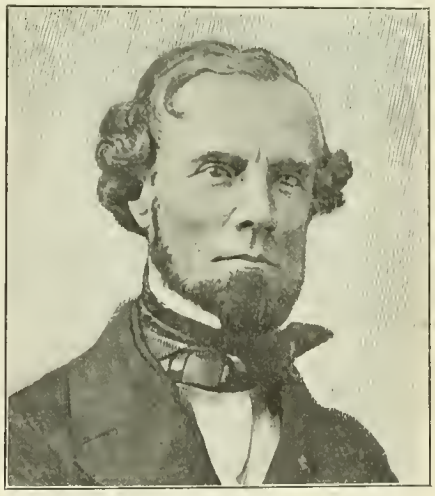
The longest active services were those of Dr. Stone, thirty-eight years; Dr. James Jones, thirty-seven years; Dr. Riddell, twenty-nine years; and Dr. Cenas, twenty-seven years.

Dr. J. L. Riddell, who held the chair of chemistry until his death in 1865, was born in 1807 and came of a family that traced its lineage back through Scottish and Irish descent to the eighteenth century. He was not merely a professor of credit to his university, but also a naturalist of international fame. He was engaged in a scientific exploration of Texas when he wrote a "Symposium of the Flora of the Western States." He discovered many new species of plants and a new genus bears his name, *Ridellia*. He was an expert microscopist in the days of the instrument's development, and as the inventor of the binocular microscope is given due tribute in that literary mausoleum of the world's workers, the "Encyclopedia Britannica."

Dr. C. A. Luzenburg, though dying when a young man, was unquestionably a man of genius. He came to New Orleans at the gloomiest time of its medical history, a poor and friendless youth, and struggled ardently to bring to life a spirit of medical interest at a time when the medical societies of the city were lying dormant. Owing to his indefatigable efforts a new society was formed—the Medico-Chirurgical Society of Louisiana. It held brilliant meetings at which the French and English physicians of the State met to exchange views, and it was undoubtedly the spirit of these meetings that caused a college building to be erected for the Medical School and that started the *New Orleans Medical and Surgical Journal*. So it was indirectly from Dr. Luzenburg and his brisk though soon spent energy that the men who outlived him received their impetus to found this medical school, which later formed the nucleus for the University of Louisiana.

The revivification of the Medical Department in 1865 was due to Dr. Richardson, who then became dean, aided by Drs. Stone, James Jones, Cenas and Hunt, and soon thereafter reinforced by Drs. Bemiss, Chaillé, Joseph Jones, Hawthorn, Mallet (now of University of Virginia), Lewis and Elliott.

Joseph Jones, M.D., LL.D., was born in Liberty County, Ga., in 1833, and was graduated as Doctor of Medicine from the University of Pennsylvania in 1855. He entered practice in Savannah, Ga., and it was not long before he was elected Professor of Chemistry of the Medical College of that city. Almost four years later he was elected to the same chair in the Medical College of Georgia. During the War he served as full surgeon in the Confederate army. Dr. Joseph Jones, a professor of chemistry in Nashville, Tenn., was in 1868 asked to take the chair of chemistry, to which clinical medicine was subsequently added at his request. He served for twenty-eight years, forming close friendships with the students and writing profusely. Three years before his death he was relieved at his request of the clinical teaching in the Charity Hospital, but continued his work and his practice in spite of failing health until his death in 1896. He strengthened the reputation of the



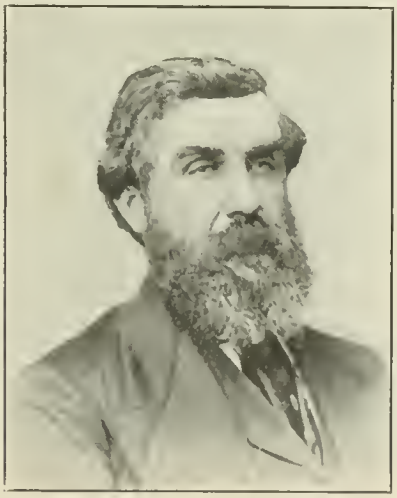
JAMES JONES, M.D.

medical department as a center of learning by his profound, erudite and vast contributions to the literature of medicine.

Dr. Samuel Merrifield Bemiss, who held the chair of theory and practice of medicine from June 15, 1866, to the day of his sudden death

AUGUSTUS H. CENAS, M.D.

from apoplexy, November 17, 1884, was not only a celebrated physician, but a man of culture, refinement and great literary ability. He was the seventh son of Dr. John Bemiss, a great physician and a great theologian. Born in 1821 at Bloomfield, Ky., he grew up in the open country



S. M. BEMISS, M.D.

and laid, through his outdoor sports, a splendid foundation of health and vigor. His early education was superintended by his father, and his medical education was obtained from his uncle, then from the University of New York, from which he received his doctor's degree in 1845. From 1853 to 1863 Dr. Bemiss lived in Louisville where he had a lucrative practice. From 1863 to the day of Lee's surrender in April, 1865, he served in various appointments as a Confederate surgeon in charge of hospitals. When he returned to Louisville he was elected professor of physiology and pathology in the University and entered again on a large practice. In the spring of 1866, however, he accepted a call to the chair of theory and practice of medicine and clinical medicine in the University of Louisiana. The affection and esteem of the citizens he left were replaced by those of the students and friends whom he made in New Orleans. He was an impressive, careful and interesting lecturer. As a clinical lecturer he was punctual in his wards and took the greatest pains with his students in teaching them the art of diagnosis, in which his superiority was very notable, and in making them self-reliant. In 1868 he became senior editor of the *New Orleans Medical and Surgical Journal*, and enriched the medical literature of

T. G. RICHARDSON, M.D.

the South by his contributions, his style and his medical perception. One of his greatest and most ardent undertakings was in connection with the great yellow-fever epidemic of 1878; he was appointed chairman of the commission for investigating its origin and spread, and was connected with the evolution of the National Board of Health and was a member thereof. His sudden death from apoplexy, November 17, 1884, cut him off at the age of sixty-three in the midst of his professional and editorial work.

A brief summary of Dr. Richardson's life, as a graduate of medicine, is requisite to an impartial estimate of the forty-four years of service given by him to the profession. Impelled by unselfish patriotism he gave for three years (1862-65) his great learning and skill as a surgeon to the soldiers of the South, to the greater credit of its medical service. As an educator he devoted thirty-eight years of active service to the instruction in anatomy and surgery of many thousands of medical students, to all of whom he

gave knowledge, inspiring them with regard for and devotion to the profession. During his thirty-eight years' service as a teacher of medicine he served three medical colleges, increasing their repute and efficiency. He gave to the Medical Department of Tulane University twenty-eight years of active service as professor, and twenty of these years as dean; during this service all the debts of the Medical Department were paid; he enriched its museum with the products of his own skilful labor; he guided the college safely through the darkest period of its history, and he greatly increased its usefulness and reputation. While administrator of the University he secured for the medical department and therefore for medical education and the profession very valuable benefits. While president of the American Medical Association he ably maintained professional reputation and dignity. He was the most influential founder of the State and Parish Medical Societies; and as a member of many other societies gave to them all greater influence and reputation. For seven years he edited medical journals and for many more years contributed to medical literature, always to the benefit of his profession. For twenty-eight years he was one of the visiting surgeons to the great Charity Hospital and no one did more than he to heal the many ills and assuage the many sorrows that always fill it. During forty years he practised surgery and medicine and inspired thousands of laymen with greater confidence in the medical profession as well as with respect for it.

Under the direction of these men and with the determination born of undaunted courage, the Medical Department made great strides to keep abreast of the advancing methods of the day. In 1887 by the valuable aid of the Tulane administrators and of Professor Ordway there was added a laboratory of practical pharmacy, with attendance therein obligatory on pharmacy students only; in 1889 the faculty established a microscopical laboratory for medical students, but a course therein was not obligatory until 1893. In this year not only were the anatomical and microscopical laboratories very much improved, but two new laboratories of chemistry and of operative surgery were established and attendance at these laboratories was made obligatory. Comparing past and present in the above particulars, it is found that, while formerly only nine different branches were taught and special courses given in two laboratories, now sixteen different studies are taught and courses are given in five laboratories. Formerly there were only eight or ten teachers, now there are forty-one; and yet more teachers are needed to teach other specialties.

The close of the war in 1865 found the college with many old books, but without catalogue, index or house-room for them; nor could a proper room be provided until the new building was completed in 1893. For several years thereafter the attention and funds of the faculty were more urgently needed for other improvements than the establishment of a library; but this was done in 1896 and it has since been annually improved. Now the college possesses, in addition to some 1,500 duplicates and comparatively useless books in an annex, a well-organized and valuable library of reference, consisting of over 3,000 properly accessioned and card-catalogued volumes. While most of these books have been donated by members of the faculty, about $2,000 has been expended in the purchase of others. This library is of great advantage to students and teachers. Another indication of progress is found in the facts that even until 1885 the medical faculty never had on its pay-roll more than five persons, while it now has twenty-seven; and, although the number of students is not twice as many as in 1885, the annual expenditures of the faculty have quadrupled. While the professors, graduates and students of the college

STANFORD EMERSON CHAILLÉ, M.D

have most notably contributed to the great usefulness and repute of the Charity Hospital, the welfare of the medical department is still more dependent on the use of this hospital for the educational purposes that are secured by law to the college. Hence, every improvement of the hospital promotes the progress of medical education. These improvements have been great and numerous, but reference will be made only to the three that have most obviously contributed to the educational advantages of the Medical Department.

Two admirable buildings were erected in 1892 for out-door clinics, and the result has been that the number of the sick seeking relief at the hospital and educationally utilizable has increased from less than 10,000 to 30,000 annually. In 1895 a new amphitheater, one of the best in the world, accommodating more than 400 students, was erected on the site of the old amphitheater at a cost of $44,130, of which $3,000 was contributed by the faculty of the Medical Department. The benefits to the diseased and injured

and also the educational advantages of this building are incalculable. In 1899 the Milliken Memorial Hospital accommodating over 200 afflicted children was erected as an annex to the Charity Hospital. For this unexcelled building the profoundest gratitude, not only of the people of this city and State, but also of the faculty of our Medical Department, is due to Mrs. D. A. Milliken.

Little more can be done than to allude to various other causes that have influenced the prosperity and educational progress of the Medical Department. But, in addition to the influence of causes already indicated, such as "hard times," yellow fever and quarantines, medical examining boards and the Charity Hospital, there are two others, politics and donations, that have had most notable influence.

The Civil War, the result of politics, influenced prosperity far more than any other cause. From 1834 to 1859 the number of students increased from 11 to 276 by normal growth. There then occurred during the next three years an abnormal increase to 404 students in 1861, due to the political and sectional hostility that induced Southern students to abandon Northern colleges. War came, and patriotic students became soldiers in such number that the 404 students of 1861 were reduced to only 94 in 1862. The doors were then closed until 1865, for, during the three intervening years, all of the students and all of their teachers, not too old for service, were Confederate soldiers.

From 1865 to 1885 the number of students ranged from 230 to as few as 105 in 1875, about which time culminated the tyrannical and monstrous evils of the "reconstruction government," based on the negro, the carpetbagger and the scalawag and upheld by the victors for the spoliation and humiliation of the vanquished South. A patriot, who lost in the battles of the South both a leg and an arm, had, none the less, enough of him still left to lead those who were determined at every risk to supplant a most vicious with a decent government. This was at last accomplished, and the people of this State, the young as well as the old, should never forget the immense debt of gratitude due to their leader, Francis T. Nicholls, who, in 1876, became the governor, and is now chief justice of Louisiana. Despair was soon replaced by hope, and prosperity began to return to the State and to the Medical Department.

From 1875 to 1901 the number of students gradually increased from 105 to 426, but it required twenty-eight years to recover from the abnormal conditions resulting from war and politics, for it was not until 1886 that the college had fairly regained the number of students that had attended in 1858. During the many very trying years that the very existence of this college was at stake, the members of its faculty gave to it devoted and skilled labor for the remuneration usually paid to very ordinary clerks.

In 1845 a constitutional convention, influenced chiefly by members of the medical faculty, ordained the University of Louisiana, and adopted as its medical department the Medical College of Louisiana, the parent of the present college. Not until 1847 did the Legislature execute the convention's decree to organize the university. This began its career with the college as its sole department. The medical faculty surrendered its building to the law department, then first organized, and was given a much larger building on a contiguous lot, where now stand the Crescent and Tulane theaters. This building cost the State $40,000, and, in addition, the State gave to the medical department, from 1850 to 1858, $43,500 for museum, apparatus and repairs. Of the $80,500 thus contributed by the State war and time have left nothing except the lot, now the property of Tulane University, and the museum still the property of the Medical Department.

The Tulane University of Louisiana derives its name from the following facts: Paul Tulane, of Huguenot descent, a resident of New Jersey, accumulated in New Orleans a large fortune as a merchant of clothing. Having experienced the need of a better education, he, unmarried, childless and advanced in years, donated in 1882 over a million dollars for the higher education of "the white young persons in the city of New Orleans," provided that the laws of Louisiana should be so changed that the property donated (real estate in New Orleans) should be exempt from taxation. This was finally accomplished, but with delay and many legal difficulties, and, to accomplish it, it was deemed best to transfer to the Tulane Administrators the University of Louisiana and thus to found the Tulane University of Louisiana. This was done in 1884 by the Legislature of the State, and this law was ratified in 1887 by vote of the people and confirmed by the State Constitution of 1898.

In 1884 the University of Louisiana became the Tulane University of Louisiana. Since then the administrators have contributed in many ways to the welfare of the Medical Department, and if they have failed to do far more that might well have been done, this has been due to the imperative need of all of their inadequate income to establish an efficient collegiate department.

Since 1886 the medical faculty, besides paying all of the constantly increasing expenses, has appropriated to improvements $17,500, derived from fees that, in less fortunate years, were all used to remunerate inadequately the members of the faculty.

In 1894 Dr. A. B. Miles bequeathed to the Medical Department $10,000, a pathetic reminder of his devotion to his Alma Mater, and a very sad and inadequate substitute for the very valuable services that death deprived him of the power to confer as a most efficient and popular professor of surgery.

The fifth and only other financial aid given to the college was by far the most important ever contributed. Without it the educational progress

that has been and will yet be made would have been impossible. May 9, 1891, the wife of Dr. T. G. Richardson, valued professor, 1858 to 1889, honored dean, 1865 to 1885, donated a sum sufficient to erect a new building, greatly superior in all respects to the old one, and especially in providing all of the laboratories that have become indispensable to medical education and that the old building could not supply. A sufficient sum to equip these admirable laboratories was also given. The administrators took possession of the lot assigned by the State in 1847 to the Medical Department, and, in its place, provided, at an expense of $35,000, a much ampler and better site for the new building. This was completed and occupied in 1893, and will continue, for very many years to come, to be exceptionally well adapted to its purpose. From this donation of Mrs. Richardson will very surely result the inestimable benefits of a better education to thousands of medical students, and, through them, relief to millions of those whom the anguish of disease afflicts and the shadow of death menaces.

Blessed is the university that has possessed such benefactors as Ida A. Richardson, Josephine L. Newcomb and Caroline Tilton; fortunate is the city that can add to this trinity such other benefactors as Deborah A. Milliken and Margaret Haughery, and discredited should be the city whose men may fail to honor these public-spirited women or may fail to imitate their beneficent examples.

THE CRAIG COLONY PRIZE ESSAY—SERO-THERAPY IN EPILEPSY.

BY CARLO CENI, M.D.,
OF REGGIO-EMILIO, ITALY;
DOCENT OF NEUROPATHOLOGY IN THE UNIVERSITY OF PAVIA; MEDICAL INTERNE IN THE PSYCHIATRIC INSTITUTE OF REGGIO-EMILIO.

(Concluded from page 442.)

Case IX.—Zelinda Brus eight years old, of delicate constitution. Birth normal. Her mother, during her pregnancy, suffered, as the result of a fright, from convulsive fits of an epileptic character. They were frequent and intense, especially in the last four months of pregnancy. After delivery the convulsions diminished by degrees, until at the end of a year they had disappeared entirely. She then entered into a state of melancholia, which lasted more than six years.

The child soon showed symptoms referable to the diseased state of the mother during gestation. The baby was scarcely five months of age when, without any determining cause, she was taken with a severe convulsive fit, which lasted about half an hour. The attack was preceded by a loud cry and a strong general trembling. After this fit the girl passed into a convulsive state which lasted more than two months, during which time the fits followed each other in series of four or five every day, with short intervals of a few minutes.

This dangerous state of things was followed by a period of almost four years, during which the convulsive fits appeared much more rarely and with intervals of one or two months. But in the spring months they grew again considerably worse, preserving the same individual character as before.

After a long period of peace, about three years ago the convulsive fits again followed each other frequently, again coming in series, four or five every day, with short intervals, especially in the morning hours.

The girl was always lively and intelligent, but peevish and extraordinarily spiteful, particularly in late years. She always showed little affection and respect toward her parents. She often ran away from home, exposing herself to every kind of danger. Of late she has amused herself by breaking everything that comes within her reach, and often, without any cause, would rush aggressively at her companions, so that it became necessary to confine her in our institution. This was in May, 1900.

The girl presents no physical anomaly. The pupils are equal and react well to light. The tendon and cutaneous reflexes are exaggerated, and the muscular tone in general is increased. There is nothing remarkable in her sensory organs. Her weight a few days after admission was 20.700 kilograms.

On the 15th of June, 1900, the treatment by the serum-injections was begun. We began with a dose of 3 cubic centimeters, and we used the blood-serum drawn from the same epileptic who had furnished the material for the patient described in Case VII.

On the day of the injection Zelinda showed no reactionary symptoms. She was good-humored, had a good appetite, and only five fits occurred. But on the following day she felt distaste for food, suffered from slight headache, and instead of being fretful and active as usual, she was dejected and silent, a state which had not previously been observed in her. The fits grew much more numerous, having occurred twelve times in twenty-four hours. The temperature remained normal, but the pulse was frequent and weak. On the following day the girl had quite recovered.

On the 18th of June the injection was repeated with the same dose as before. She looked dejected and confused a few hours after the injection. The pulse was more frequent than usual and the temperature toward evening reached 38° C. No convulsive fit occurred that day. However, the girl suffered from much confusion of the mind, with slight symptoms of paresis of the lower limbs, attended by a remarkable increase of the tendon reflexes. All these phenomena soon disappeared, and on the following day the girl was in her normal condition. On the 19th the convulsive fits recurred nine times.

On the 22d of June we made another injection, again with the dose of 3 cubic centimeters. No noteworthy symptoms resulted. The temperature was normal and the fits came with intensity and frequence. On the day after the injection the only change noted was an exaggeration of her usual restlessness.

On the 26th the injection was repeated, but with the dose of 4.5 cubic centimeters. A few hours after the injection the girl looked dejected and sleepy. The pulse was weaker and more frequent than usual. The temperature rose to 38° C., in the night reaching 39° C.

Let us remark once for all that at the point of injection no reactive effect was ever observed.

On the 27th the condition of the patient rapidly improved. The temperature, which all day had been 38° C., returned to normal toward evening. The girl, however, was very much dejected all day, with short periods of great motor excitement, during which she made such disorderly movements as to suggest chorea. In these last two days there were no real convulsive fits.

On the first of July we injected 5 cubic centimeters of the same serum. It was tolerated without great inconvenience. The little girl was only more restless than usual. The fits followed each other as frequently and intensely as ever. The weight was 19.600 kilograms, a decrease of more than one kilogram.

Afterward, in the month of July, five injections of the same serum were given in progressive doses. At the last injection, performed at the end of the month, we reached 10 cubic centimeters at a dose without Zelinda presenting any trouble worth noticing. She was constantly good-humored and gave no sign of entering into the state of depression which followed the first injections. Her general condition was the same as before the treatment. The convulsions, however, came more frequently than formerly, occurring from five to ten times every day. She was still peevish, spiteful and disorderly. She weighed 20.500 kilograms.

August: As the epileptic manifestations, instead of getting better, get worse, in this month the serum injections are interrupted. However, she continues in the severe convulsive state of the preceding months. Besides, the motor crises are more frequent than formerly, reaching several times the number of twelve and more in twenty-four hours. Her weight is 20.300 kilograms.

September: Still no injections. The girl continues in the same severe condition as during the two preceding months, being very restless and having frequent convulsions. Her weight is 21.500 kilograms.

October: As a last and definitive experiment we begin injections again. Instead of employing the same blood-serum as was used previously, we now have recourse to the blood-serum obtained from another epileptic, as seriously ill as the first one. We again employ increasing doses. The girl bears the injections well, and presents no mediate disturbances. The dose of 10 cubic centimeters is soon reached, and in this month a total quantity of 32 cubic centimeters of serum is injected.

Although the little patient did not react to these injections with acute and direct phenomena, her general condition became worse again by degrees, with great increase of the motor crises. Towards the middle of the month she went into a severe convulsive state, having twelve to fifteen fits in the twenty-four hours. On the 26th of the month she developed a total paraplegia which came on suddenly. The girl was stupid in expression. She uttered but a few words and then with a peculiar hesitancy of speech. She had involuntary passage of urine and a copious salivation. The pupils were unequal and reacted feebly to light. The general reflexes and particularly the patellar ones were extremely exaggerated. Her weight went down to 19.700 kilograms.

This state of affairs lasted until the first days of the following November, when a general improvement began. The paralysis of the lower limbs disappeared rapidly, first on one side and then on the other. By the middle of the month the girl could walk without being supported and only presented a slight degree of paresis, but severe convulsions again occurred frequently.

In November, and especially in December, the motor crises also were remarkably diminished in number compared to what they were in the preceding months. The weight went up to 20 kilograms and later to 21.500 kilograms.

In January, 1901, the girl was in about the same condition as she was before the injections. In the whole month she had 147 convulsive fits, but they were not all intense.

In the ensuing months, until the end of May, her general condition remained almost unvaried. The motor crises were about five a day, coming especially in the morning hours. The convulsions have become rather less intense than before. Since the injections were definitively abandoned, the girl has received one gram of bromide daily.

	Diary of the Convulsions.	Weight in Kilograms.
May, 1900	125	20.700

Case X.—Maria I., twelve and one-half years old. She has no hereditary stigmata and never suffered from any important disease. She grew up healthy, showing precocious physical and intellectual development until the age of three years, when, in consequence of a fright through being forced to bathe in a river, she gave the first signs of her present disease. A few hours after the bath she had three fits, evidently of epileptic nature, which followed each other within the short interval of a few minutes. From this time the fits increased in number and severity. For the first two years the convulsions occurred once or twice a month, but then they grew by degrees more numerous, until they recurred four or five times a day, following each other at intervals of three or four days. The patient has now been for about three years in this severe condition, although the bromide treatment in very high doses has been frequently tried.

The convulsive fit is complete. It lasts from ten to twenty minutes with violent muscular shocks. It is always preceded by a feeling of anguish and faintness, attended by an intense and painful contraction in the epigastric region. For some time these auræ have occurred with extraordinary frequency, from three to seven times in the twenty-four hours. But they are not always followed by convulsions, which, as I have stated, present some periods of two or three days' intermission. During the motor crises the girl becomes very cyanotic and often voids urine. The crisis is always followed by confusion and depression, lasting about one hour.

With the increase of the fits the patient's physical development was checked and her intelligence gradually grew more feeble. At the same time an evident change of character was observed in her, and from being good and gentle, she became wrathful, disobedient and spiteful to everyone. She never went to school and does not even know the alphabet. Being incorrigible and having got in the way of exposing herself to danger and to running away from home, she was admitted to this institution.

The patient is of backward physical development. Nothing remarkable as regards sensibility and motility. The reflexes are rather exaggerated. She is not very intelligent. She pays little attention to what happens about her, and answers questions more by signs than by words. Her dress is disordered. Her weight in the months of August and September, 1900, was about 31.500 kilograms.

October 1, 1900: The serum-injections are begun, and the bromide treatment is stopped. The serum is drawn from another epileptic and the total quantity injected in the first month is 48 cubic centimeters. From the onset the patient tolerates the treatment well. Both the motor and sensory crises are reduced in this month to about one-third of what they were in the preceding month. Yet their character is the same as before. The nutrition of the girl rapidly improves, so that her weight increases to 36.600 kilograms.

November: Sixty-five cubic centimeters of serum in all are injected. The motor crises are limited to five, all of which occur in the last week of the month, after about thirty days of complete pause. Meanwhile the girl's temper is much changed. She has grown good and mild. She has a rosy color and looks livelier and more intelligent. She dresses with more care, and spends the day with the sewing-women, for she wishes to learn to sew. Her weight increases to 38 kilograms.

December: The total quantity of serum injected is 80 cubic centimeters and the girl gets on very well. Her weight increases 1 kilogram more. She has five motor crises and two sensorial ones. The crises appear to be less intense and shorter than formerly. The girl behaves in an exemplary manner and looks healthy. Toward the end of the month she begins to go to the school of the institution, where she soon shows herself eager and diligent.

January, 1901: The quantity of the injected serum is 65 cubic centimeters. Her condition remains unvaried. The number of crises is about the same as in the two preceding months. She weighs 40 kilograms.

February: Injected serum 70 cubic centimeters. While the general condition is still very good and the weight reaches 41.500 kilograms, the epileptic crises on the contrary become a little more numerous.

March: Total serum injections reach 80 cubic centimeters. The general state of the patient remains unvaried and the crises recur with the same frequency as in the preceding month. Toward the end of the month the girl has her menses for the first time, although she is but thirteen years old. They continue afterward regularly.

April: The injections are stopped. The girl continues to be as improved as in the preceding months.

May: Her weight is 39.700 kilograms, and the number of the crises remains much smaller than it was before the treatment. She looks like a full-blown, healthy, intelligent girl, quite different from what she was formerly. Now she is looking forward to the time when she is to return to her family.

Diary.

A general glance at the histories of the cases of epilepsy in which the new curative method has been tried, quickly convinces us that the great difference in the results in the different individuals constitutes the part of these researches which most demands our attention.

Indeed, if we consider the results so far obtained, we may divide the patients into two well-distinguished groups, viz., those with a positive result and those with a negative one; for, while this method proved very successful in some cases, in others it did not suit at all.

Let us see what patients belong to these two groups and what clinical facts distinguish the ones from the others, during the long period they were under observation.

We must remark first of all that, of our ten patients of different ages chosen expressly from among the severest forms of epilepsy, eight belong to the first group. They are represented by Cases I., II., III., IV., V., VI., VIII., and X., in all of which distinct advantage was derived from the treatment, though in different degrees. Two cases belong to the second group, viz., Cases VII. and IX., in which the serum-injections not only were not beneficial, but were contra-indicated.

Now, I will state the kind and degree of benefit the epileptics of the first group derived from the treatment. We shall see later what clinical phenomena of scientific interest were presented by the epileptics of the second group.

Group I.—Positive Results. Cases I., II., III., IV., V., VI., VIII., X.

In order to distinguish the cases with positive results from those that did not receive the least advantage from the treatment, two principal facts demand attention, viz., the manner in which the patients reacted to the first injections and the nature of the final results. Both of these phenomena were often remarkably different in different individuals. As to the manner in which the patient reacted to the first injections, we observe that some patients accommodated themselves soon and easily, without experiencing the least inconvenience, while others exhibited at first a peculiar intolerance.

The former, although at first unchanged, soon showed a more or less remarkable and progressive improvement. Thus it was with Cases III., IV., V., VI., and X. The two patients described under Cases I. and II., after the first injection, exhibited the phenomena of an acute intoxication which consisted chiefly in a rapid diminution of weight, and in an increase in number and intensity of the motor crises.

One of them (Case I.) exhibited besides in this period continued drowsiness, which was not usual in her. It lasted about five days and was attended with evident symptoms of paraparesis.

The period of accommodation being over, both of these patients entered, in about a fortnight, into the period of general progressive improvement, into which the other six patients of this group passed directly; so that within a month from the beginning of treatment all the epileptics of this group had been benefited. The gradual improvement from the first month, in nutrition and in weight, the progressive and often remarkable diminution of organic disturbances in general, and especially in those affecting digestion and circulation, gave incontestable proofs that these epileptics were undergoing organic modifications that gave promise of great future success.

To give an idea of the enormous influence that the injections had upon the general state of the patients, I will recall the deep modifications that took place in Adolfa C. (Case I.) in a few months. After an initial period of crisis during the accommodation to the first injections, though we had stopped by degrees all the symptomatic drugs she had been taking so long, the patient passed quickly into a state of physical well-being that surpassed all our hopes. The girl soon

gained 6 kilograms. She lost by degrees the habitual cyanosis of the face, her complexion becoming even florid. Her skin grew everywhere soft, bright and rosy, even in the parts that had been covered with a painful erythema. It will be remembered that this erythema had lasted a long time and had resisted all treatment. The circulation became active again; all the severe digestive disturbances disappeared and during the third month of treatment the menses returned, although they had been absent for more than one year. The obstinate insomnia also disappeared in a short time. The girl was like a healthy person.

We have a similar case in Maria I. (Case X.), epileptic for nine years and physically much inferior to the preceding patient. In consequence of the injections a change was so rapidly effected that after four months the girl looked much better and was about 10 kilograms heavier. In the fifth month of the treatment the menses appeared for the first time and have continued regularly.

In Cases VI. and VIII. we may observe still more convincing proof of the extraordinary influence the serum-injections may have in stimulating nutritive change, even to exaggeration. The physical condition of these two little patients (Armida Gib and Albertina Bus) changed so much in a few months that the girls were not to be recognized. In seven or eight months they doubled in weight and, their complexion becoming florid, they looked like healthy persons. The former began to menstruate regularly when twelve years old. She weighed 60 kilograms.

The improvement in general nutrition which took place in all the epileptics of the first group was not always the same in manner or degree. In some patients there was gradual improvement from the onset which ceased after a few months. In others the improvement was more prompt and continuous. The former exhibited pauses and slight relapses; the latter went progressively and steadily forward.

The first mode of improvement is especially characteristic for those patients who attained a certain degree of benefit from the treatment, but then remained stationary, although the injections were continued. The weight that these patients gained during the period of reaction, that lasted from six to seven months, oscillated between 6 and 10 kilograms.

The second mode of improvement, *i.e.*, that characterized by a rapid and progressive gain, was shown by those epileptics who, at least till the present, give us reason to hope for a real recovery. Since the treatment of the first two or three months, in addition to the total disappearance of all epileptic manifestations, they grew from 10 to 20 kilograms heavier, an increase that did not cease even after the treatment was stopped. Cases VI and VIII. gave this result. The former patient has now been more than one year in the state of a perfectly normal person. Before the injections she weighed 34 kilograms. She now weighs 60 kilograms. In Case VIII., the patient, after about six months of general well-being and of total suspension of the epileptic manifestations, had a slight and transitory relapse caused by a bronchitis. She, too, recovered, after the disappearance of the bronchial disturbances.

An idea of the manner of improvement in general somatic functions in consequence of the treatment is given by Case V. In this patient we saw a gradual disappearance, which in time became almost total, of a complication of the severest disturbances of sensibility, motility, general reflexes and of vegetative life.

The quick transformation in the psychic personality of the patients, even of those in whom degeneration and defects in intellectual activity were profound, excites the greatest interest. Even in the severest cases, as for instance in Cases III. and V., we have witnessed a real, though slow, arousal of the psychic powers. The recovery of the intellectual and affective functions was always last, appearing after the physical condition had reached normal or the highest improvement possible.

A forceful example of the influence that serum-injections may have in arousing the intellectual faculties of epileptics is given us by Armida G. (Case VI). This patient entered our asylum when eleven years old. She did not know the alphabet and seemed almost completely demented. In her general state she was like a brute. After a few months' treatment she was able to go to school and proved to be fairly intelligent.

Even in facial expression the patients underwent remarkable changes. This was especially true for Cases II., VI., VIII., and X. As the patients improved physically, they became commonly more active and of more normal appearance. At the same time, they grew more and more orderly, particularly in regard to dress. As to the girls, they showed in time an inclination to dress well, perhaps even better than their rank and age justified.

Generally our epileptics who formerly were tiresome, peevish and even aggressive, became of a milder and more sociable temper and behaved like normal persons. But unhappily these benefits were not always permanent.

In the two patients described in Cases VI. and VIII., besides the rapid improvement in physical and psychic condition, there was a complete disappearance of all epileptic manifestations. In them there seemed reason to hope for a real recovery. But the other six patients, after a few months of more or less remarkable improvement, entered into a new stage, which is probably the beginning of a relapse, though it has not as yet proved so.

The following are the principal characters of the descending parabola of the general condition of these six patients. It proceeds with fairly distinct interruptions.

The increase in the number of the motor crises, though the patients may continue to show for some months a physical and psychic gain, has been in every case the first symptom. In adults this increase generally happened much sooner than in young people. I think that in these latter it may be possible, by continuing the injections, to prolong the improvement. In the older patients, however, the injections soon lose their effective power and are of no use in warding off a relapse. However, in both cases the number of motor crises remains smaller than it was before we began the injections, one and two years ago.

For example: Adolpha Cam. (Case I.), a severe epileptic for many years, had convulsive fits that used to come a hundred or more times a month. These were reduced during the treatment to an average of three or five a month. On stopping the treatment the fits soon increased to about twenty a month. The girl has now been in that condition for more than one year, that is, since she returned to her family.

The same may be said of the lad Paul Rov. (Case II.), whose crises, from an average of fifty and more a month, went down to three or four during the six months of treatment. About two months after the patient had returned home, that is, two months after the interruption of the injections, the number of crises increased again but was still much smaller than at first. This fact is still more evident from the complete diaries of the epileptics who are still under direct observation.

In general, within a few months after the injections

were suspended, we began to observe a deterioration in the physical condition of all these patients, which in the severest and oldest cases was soon followed by a return of the psychic and psychosensorial phenomena.

Neither this new physical deterioration nor the reappearance of the psychic and psychosensorial phenomena has as yet assumed the dimensions of a total relapse. In no patient has the body weight descended as low as it was before the injections; and even the psychosensorial phenomena have not yet attained the severity they had before the treatment.

Case V., that of Pius Rom., who stopped the injections about one year and a half ago, is a pertinent example. For nearly one year the monthly number of fits was from five to six a month, while in the preceding years it was from twenty-eight to thirty; the weight is 6 kilograms greater than it was before treatment and the psychic state is much better than before. The patient still has periods of mental confusion attended with hallucinatory phenomena, but they are short, transitory and less intense than previously. He is fairly orderly and has given no sign of falling again into the brute state he had long been in before the treatment and in consequence of which he had been shut in the department of the filthy.

We may say the same of all the others; for instance, of Adolpha Camp., whom we have mentioned in speaking of the motor crises. This patient, having returned home in consequence of the remarkable improvement gained through injections, suffered some months later from an increase of the fits. But the manifold psychic and psychosensorial phenomena that first had caused her to be confined in this institution have not as yet returned.

Therefore, we may say that even in the cases in which the benefits obtained by serotherapy, consisting in an improvement in the general condition of the patients or in a more or less remarkable diminution of all epileptic manifestations, are only transitory, they are none the less of sufficient duration to commend the treatment to general consideration.

Group II.—Negative Results. Cases VII. and IX.

Two cases belong to the group of negative results, Cases IX. and VII. These patients not only did not give any sign of improvement after the serum-injections, but grew worse physically and mentally. Both of these epileptics reacted to the first injections in the same manner as two of the cases belonging to the group of positive results. In passing through the period of accommodation to the treatment, they grew worse, especially as to the epileptic phenomena. They gave, however, a very different final result from those of the group of positive results. For in these latter it was a question of a transitory crisis of accommodation with acute phenomena followed by a state of general benefit, while the former gave evidence of a slow progressive intoxication which was characterized by an increase in number and intensity of the epileptic phenomena.

Charles M. (Case VII.) got so slowly worse in the first week of treatment that we hardly perceived it. He seemed to be unaffected by the injections. In the second month of treatment, however, he began to exhibit a slight diminution in weight and an increase in the epileptic manifestations.

Zelinda Br. (Case IX.) after the first injections soon developed what I call a crisis of accommodation. It had the characters of an acute and alarming intoxication with elevation of temperature and a rapid increase of the epileptic phenomena, especially of those of psychic nature. But even in this case the acute phenomena soon disappeared and the little patient, after a few weeks of peace, during which her general condition was the same as before treatment, grew worse. Her weight diminished and the epileptic crises increased alarmingly.

On suspending treatment these two patients by degrees returned to their original state. Evidently, therefore, the injections had been the direct cause of all the disturbances. I will not speak now of the importance that these negative results have from the scientific point of view. But I will observe that from the different and contrary manner with which patients react to injections we may draw important prognostic points as to the final issue of this treatment in epilepsy.

I have already tried to call attention to the remarkable difference existing between the quick, imposing, progressive increase in weight of the epileptics considered as recovered, and the slow, interrupted and limited way in which the weight increases in those patients who only improved. As just observed, the epileptics who received no benefit from the treatment (Group II.) not only never exhibited an appreciable increase in weight, but when the injections were continued they lost in weight. These three peculiar modes of reaction have preserved their distinct characters so constantly that we may, perhaps, depend on them in making a prognosis, though my observations are perhaps too limited to permit inferences of a general nature.

Let us see what are the causes of such different and contrary effects in the beginning as well as in the final issue of the treatment; and whether any clinical facts or anamnesic data in the individual cases can be regarded as helpful in prognosis.

Now the question arises whether the causes of such different and opposed modes of reaction on the part of the patients suffering from epilepsy and undergoing the same treatment exist in the subject himself or in the epileptic who furnishes the material for the injections.

We can only have an entirely satisfactory answer to this question in the light of further observations, and especially observations on younger subjects, who have furnished the most decisive and interesting results from every point of view, both practical and scientific. Still I think we can even now obtain some data from the actual results before us as evidence. It certainly seems as though the different and opposite results so far obtained have their source in the organism of the patient injected and not in the organism of him who furnished the serum.

Here are briefly the facts leading us to this inference. First it must be remembered that our epileptics, though they all were treated in accordance with the same principle, underwent two methods of treatment which, in appearance, at least, were different. Some patients received injections with serum drawn from the blood of other epileptics, while in others auto-serotherapy was the method. In Cases III., IV., V. and VII., this latter method was employed. The results were good only in the first three cases. In these there was marked improvement without the least inconvenience. But in the fourth case (Case VII.) it was quite different, for the patient grew progressively worse, the weight diminishing and the epileptic manifestations growing considerably worse. He exhibited none of the acute phenomena observed in some other cases, but continued for some months to get slowly and progressively worse. We may then suppose that the individual organic condition of this patient could not tolerate an artificial increase of the toxic principles already circulating in his organism and that this increase constituted the most direct cause of the deterioration.

Later we tried in this patient injections of serum derived from other epileptics, but his condition again grew worse and worse. It is then evident that the cause of the negative result in this case is to be looked for in the patient himself.

We arrive at the same conclusion and perhaps in a still more evident way, when we compare the results in the Cases VIII. and IX., in which the injections were of serum drawn from the blood or other epileptics. These two patients were girls of about the same age, degenerated physically and severely epileptic. For two consecutive years the fits were intense in both, and occurred 100 and more times a month.

Now these two patients were almost contemporaneously subjected to injections of blood-serum drawn from the same epileptic. From the beginning they gave very different and contrary results. The first, Albertina B., entered soon into a state of progressive well-being, which was marked by a quick diminution and then by the complete disappearance of all epileptic manifestations and later by great increase in weight. On the other hand, the second, Zelinda B., reacted to the first injections with alarming symptoms of an acute intoxication (elevation of temperature, great depression followed by psychomotor excitement, severe confusion of the mind, etc.). She entered later into a slow and progressive period of getting worse in her general condition, with diminution of weight and a great increase of the epileptic crises. After about two months she bade fair to enter into a continual epileptic state.

The evident contrast in these two girls of the effects of injections with blood-serum of the same origin shows, I think, that the peculiar condition of the patient constitutes the chief cause of the different final issue.

What, then, are the causes leading to such contrary results? In several important ways the history of the patient helps us answer this question. My studies have convinced me that between certain anamnesic data and the final issue of the treatment there are constant and interesting relations.

The hereditary nature of the disease, the age of the patient at the time of its appearance, and its duration before treatment was begun are the important points.

Thus of our patients, the ones in whom the result was negative were cases of hereditary epilepsy. The two negative cases are that of Zelinda B., nine years old (Case IX.), who, born of an epileptic mother, exhibited severe symptoms since three months of age; that of Charles M., forty-six years old (Case VII.), had severe hereditary stigmata on both paternal and maternal side, and was an epileptic from early childhood.

In the eight others whose epileptic manifestations ceased for awhile or permanently, or who grew only better, hereditary stigmata were either absent, or, if present, the epilepsy had manifested itself late in life and commonly from an accidental cause.

The benefits these patients received from the treatment were generally more evident in those cases in whom the epilepsy was recent than in those in whom it had existed for a long time.

The two cases considered cured had no hereditary precedents. In them the first epileptic symptoms appeared about three years before treatment. In the other six cases that only grew better, the disease had existed for ten or twenty years and even longer. One of these patients (Case II.) was epileptic for five years only, but he was also the only one with severe hereditary predisposition.

Thus, from our cases it is evident that the hereditary forms that manifest themselves from childhood are the least suitable for the serum treatment, while the acquired forms of recent date give the most satisfactory results.

Further observation must decide whether the conditions above mentioned are the only ones that have to do with the very different ways in which epileptics react to the treatment. I think, however, that both the positive and negative results obtained by my experiments have great importance from any point of view.

The next question is, Is the effect obtained in epileptics due to a property peculiar to the serum of epileptics or to a property of human serum in general? To answer it control experiments are necessary. Accordingly, I subjected other epileptics to a treatment of continued injections, using the same method as before, but getting the serum from normal persons. In all six patients, chosen from the severest forms of epilepsy, were injected. I will limit myself to a short résumé of their histories and the results.

These subjects of control were as follows: A very severe case of a patient, thirty-seven years old, with hereditary epilepsy; four cases of patients from twenty to forty years of age, with acquired epilepsy that had existed for from ten to twenty years; and the case of a patient, fourteen years old, with acquired epilepsy of five years' duration. All received for three months injections with blood-serum drawn from healthy persons. None of them ever exhibited a diminution in the number of the attacks, or any improvement in health whatever.

In one case of acquired and inveterate epilepsy, there was a slight increase in the morbid phenomena. In all others the number and intensity of the crises did not change during or after this period of experiment. Countenance, character and mental state remained unchanged.

As to general nutrition, in one case, that is, in the youngest patient, who had been epileptic only five years, there was an increase of about 4 kilograms in weight. In the case of hereditary epilepsy and in two cases of acquired epilepsy, the state of general nutrition and the weight remained practically the same as before the injections.

The two cases of acquired and inveterate epilepsy grew worse generally, and in a period of three months diminished from 3 to 6 kilograms in weight. One of them, as already stated, exhibited also a slight increase of the epileptic crises. In about one month after the suspension of the injections, however, these two returned to their normal condition.

The contrast between the results with injections of the blood-serum of epileptics and those obtained by injections with serum of healthy persons, makes it evident that the power of determining the deep modifications in the condition of epileptics resides in the serum of the epileptics themselves and not in human serum in general.

However, although injections with normal serum have never exhibited and effectual anti-epileptic power, they have a certain analogy with injections of epileptic serum. The analogy is that some cases grew worse in consequence of injections with epileptic serum as did two from injections with the serum of normal individuals. Such an analogy, however, does not weaken the conclusion already drawn, namely, that the property of determining deep modifications in the symptoms of epilepsy belongs to the serum of the epileptics themselves.

Through injections with the serum of healthy persons we never obtained the clinical picture of acute or chronic intoxication such as we obtained with epileptic serum. It is to be noticed that while both acute

and chronic symptoms of intoxication by epileptic serum were characterized by an increase in number and intensity of the epileptic crises, the injections with normal serum caused a progressive deterioration in the general nutrition of the patient but without much increase in the epileptic crises. Also the two patients that grew worse in consequence of the injections with normal serum were restored to their habitual condition in about a month after the suspension of the injections; but the two patients that got worse after the injections with epileptic serum went several months before they returned to their normal state.

Although the number of negative results are small, the conclusion to which they would seem to point agrees with the modern autotoxic theory of epilepsy. Otherwise, we would have to believe that the same soluble toxic principles, now considered as the proximate cause of epilepsy, circulate in healthy persons and in epileptics. It may be that the epileptogenous principles are but exaggerations of physiological principles circulating in healthy individuals, for certain phenomena occurred in epileptics from the injection of normal serum. But if these are the same in kind, they certainly differ widely in degree. That is, however, largely hypothetical.

It seems in every way probable that the cause of the different and opposite effects obtained by injecting epileptic serum exists, for a great part, at least, in some organic condition of the patient into whom injections are made, and not in the person furnishing the serum. The same may be said of the injections into epileptics of serum of healthy people. This past month I have employed in my control experiments, both in the cases that remained indifferent to the injections and in cases in which a bad reaction occurred, the serum drawn from different persons than those who had furnished the serum in the preceding months. In both the results were the same.

This simple observation indicates that even the blood-serum of healthy individuals, as well as that of epileptics, contains some soluble principles that generally do not act like toxins when injected into the organism of epileptics, but that they may so act when the injected epileptic exhibits peculiar organic conditions which are altogether unknown to us.

Though the toxic effects determined by epileptic serum may be more severe and of a more specific character than in those determined by the serum of healthy persons, they nevertheless furnish a point of intimate analogy between the soluble active principles circulating in human blood in general and those circulating in epileptics. Such an analogy supports the opinion that the epileptogenous agents are but exaggerations of the physiological products that circulate usually in human blood.

It is only an hypothesis, and I advance it cautiously. But I wish to emphasize what may be of importance in the etiology of epilepsy, that in some cases injections with epileptic serum are contra-indicated.

Of course, the greatest interest of my experiments centers about the cases that have undergone a diminution or a complete disappearance of all epileptic phenomena. What meaning and value can we give to these results?

I think, above all, that the facts we have now before us cannot be interpreted by assuming an occasional immunity to epileptogenous toxins. According to the opinion we have of immunity, that it is conferred by habit and that it is generally obtained by progressive doses of mineral or vegetable poisons, we may suppose from our experiments that repeated injections with epileptic blood-serum may determine in other epileptics an increase of resistance to the fits. But we cannot go so far as to admit that such immunity would result in a complete and lasting suspension of all epileptic manifestations, as occurred in two of our cases.

Absolute immunity to a toxic agent conferred by habit would be strange and inconceivable, especially in such cases as ours in which it would have had to be produced by a small and artificial increase of a toxin that had long circulated in the organism.

Immunity by habit could, moreover, explain neither the deep modifications in nutrition nor the quickness of the therapeutic effects.

The question of a probable process of vaccination also presents itself. The modification in nutrition, one of the most important effects of our serum-injections, seem to correspond to the process of immunization itself; for we know from pathology that, for the greater part, resistance due to any form of vaccination whatever, is but the expression of nutritional changes. But the nutritional modifications in our patients appeared so quickly and to such a marked degree that I think even this last hypothesis does not suffice to explain the final results. For immunity, caused by vaccinating principles, usually proceeds very slowly and takes many days to establish itself.

The relation between the nutritive modifications and the immunity conferred by serum-injections has, in our cases, been more intimate and direct than we can imagine in any process of vaccination. The improvement in nutritional conditions, inferred from the considerable increase in weight of the patients, most frequently preceded the diminution in epileptic crises. In every process of immunizaton, however, resistance conferred upon an animal keeps pace with the nutritive modifications. These latter, moreover, are never so pronounced as in our epileptics. Further, if the epileptogenous toxic principles possessed vaccinating properties, an epileptic bearing these principles in himself would at length undergo a natural auto-immunization, and such immunization could not be obtained artificially by injecting into another epileptic some cubic centimeters of blood-serum that contains the same inoculating substances as his own blood contained. Finally, if epileptogenous principles have vaccinating properties it is impossible to understand how these properties may, in some cases, cause the symptoms of epilepsy to become progressively worse.

Therefore, the data we possess upon the mechanism of action of the active principles contained in the blood-serum of epileptics speaks against their having a vaccinating power; on the contrary, I think the same data demonstrate that it is probably a question of principles that are restoring and therapeutic at the same time. This opinion is sustained, as I have remarked, by the quick appearance of the beneficial results and still more by the intimate relations of time and degree between individual results.

I have become fully convinced that the improvements in general nutrition represent the return to normal of the organic elements. In all probability these elements constitute the seat of elaboration of the epileptogenous toxic principles and thus represent the anatomic basis of epilepsy itself.

The mediate influence of the organic modifications upon the final therapeutic result of injections has been too evident and constant in our epileptics to draw a different inference.

Therefore, the nutritive modifications in the present experiments are not due (as is now generally admitted for the different processes of vaccination) to the properties that the active principles have of modifying the nutrition and of allowing the cells to make elements

pernicious to bacteria or their products; but they are due to a direct action exerted by an active principle on the cells concerned in metabolism which are already in physiopathological conditions. The morbid condition of an epileptic would thus be subordinated to the said organic modifications, and the active agent contained in the serum would act in an indirect manner only.

This active principle of the blood-serum of epileptics, which is capable of determining in epileptics themselves a restoring and therapeutic action, may then be considered only as a principle which stimulates metabolism. So that henceforward it cannot be confounded with the anti-toxic principles of immunizing serum of microbic nature, which are the chief basis of modern serotherapy.

The mechanism of action of epileptic serum and those of microbic serum and of antitoxic serum are too different to permit their active principles being regarded as of the same nature, though they may seem to be so at first sight.

The antitoxic theory in the chemical and neutralizing sense, as maintained by Ehrlich and his disciples, as well as in the biological immunizing sense as maintained by Bouchard, Metchnikoff, Charrin, Roger, Vaillard, Roux and many others, could not at all explain the negative results obtained by the injections of epileptic serum, and to which we attach great importance for the pathogeny of epilepsy. The opinion that a stimulating principle is contained in the serum of epileptics, on the other hand, helps to explain the positive results and the negative ones also.

We have already proved that the chief cause of the different and opposite results secured by this new serotherapeutic treatment is dependent upon some peculiar and individual organic conditions in the epileptics who undergo it. We have already remarked, also, that some intimate relations of cause and effect must exist between the epileptogenous agent and clinical results. Therefore, I think it will now suffice to subordinate the action of this active stimulating principle to the peculiar pathological conditons of the elements of the changes in the various epileptics, in order to find the reason, for which the said continued injections may produce effects of such a different and opposite nature.

The influence of the individual pathological conditions on the final results may be due to the former being in some cases of a character to allow to the cellular elements (representing the probable anatomical substratum of the changes and of the epileptic manifestations) a physiological reaction to the mentioned stimulus: while in other cases the cellular elements are in a condition to deprive them of all power of a physiological reaction. In the first case we would have a positive reaction with the anatomical elements returning partially or wholly to their physiological state, *i.e.*, a diminution or disappearance of the circulatory epileptogenous toxic principles. In the second case, on the contrary, the reaction would be negative. The anatomical elements, under the influence of the stimulating principle, would get a pathological hyperactivity with a consecutive hyperproduction of the epileptogenous principles. These two cases would show clinically a diminution or total disappearance of all epileptic manifestations or an increase of them. Illustrations of both of these cases are furnished by our experiments.

Even the benefits of auto-serotherapy in epilepsy would find a plausible explanation by assuming a stimulating principle. In auto-serotherapy it seems to me that both the state of acquired immunity for accommodation or for inoculation, and the action of an antitoxin are to be *a priori* excluded. For the immunizing principles as well as the antitoxic ones, if they circulated in the organism of an epileptic, should exercise their beneficent action when circulating in the organism of the individual in whom they were formed. Also, were they really immunizing or antitoxic principles, they would never cause the general condition of the individual in whose organism they were elaborated to get worse, as we have seen in one case.

We must then admit even here a stimulating principle to metabolism, as we have done for the other cases. For it is no longer the serum of one epileptic which exerts a stimulating power to the metabolism of another epileptic, but the same blood-serum, inert in its physiological state, which now possesses that property. So we must believe, in general, that the serum of epileptics receives its stimulating property from the organisms of epileptics only at the moment it ceases being a physiological vital humor; that is, when it ceases circulating in the body and comes in contact with the external air.

We are then obliged to admit an active principle, that, in the physiopathological condition of an epileptic, exists in the blood in a latent state only. It is soluble, is perhaps bound to the anatomical elements of the blood, and in its free state grows active when these elements cease living.

Therefore, I think the theory of a stimulating principle, which, depending perhaps on a nervous influence, causes the manifestations of epilepsy to get better or worse, is the most reasonable to explain the different results I have obtained by continued injections with serum.

There remain a few words to be said concerning the meaning of the symptoms of the acute transitory intoxication observed in some epileptics. They appeared in direct consequence of the first injections with serum drawn from other epileptics. The nature of these symptoms, their sudden appearance and disappearance, and their transitory character are, I think, sufficient to indicate a crisis of accommodation to a new poison introduced into the organism. Therefore, it seems impossible to confound the cause of these acute direct phenomena with the causes of the chronic slow and progressive deterioration observed in other cases as the final results of continued injections.

That these crises of accommodation were never remarked after injections with blood-serum of healthy individuals (which might have been supposed after Bouchard had demonstrated that injections with blood or with blood-serum could not produce any toxic manifestations when they are made into animals of the same kind) is a direct demonstration of the presence of a poison which is soluble in the blood-serum of epileptics, but which does not exist in the blood-serum of normal individuals. These crises of accommodation characterized by motor and psychical epileptic manifestations, are not to be confounded with such accidents of modern serotherapy as polymorphic eruptions, exanthems and arthralgias. In the two cases the phenomena are different in nature and pathogeny. The accidents caused by immunizing serum are to be ascribed, at least according to some authors (Landouzy, "Serothérapie," Paris, 1901), only to the coefficient of the toxic power peculiar to the serum of the animal that has supplied it. These accidents are explained by the introduction into the human body of a serum obtained from an animal of a different kind. In epileptics the crises of accommodation are caused by serum of the same kind, but which has been drawn from an individual in a pathological state.

Only one objection can be made to this interpretation of the crises of accommodation. It is this: If it is really a peculiar toxin of the blood of epileptics that

determines the severe symptoms of an acute intoxication, why does it not do so in all epileptics undergoing these injections? It was noticed only in a few.

We answer this by saying that the individual organic conditions of the patient into whom the serum was injected may entirely modify the characters and intensity of the phenomena of reaction to the toxin of which we are speaking.

We have already seen that the positive or negative final result depends almost exclusively on the individual organic conditions of the epileptic treated. Now I think it even more justifiable to maintain that the different modes of reaction and accommodation to a toxin that is introduced into the organism are dependent upon individual conditions. For we know the extraordinary importance that the individual state and natural immunity may have, not only for the different and opposite resistance to the actions of poisons in different animals, but even in the same animal, as we see also in human pathology.

The resistance to the toxic power of blood in general varies in animals of the same kind, as is proven by a series of experiments I have made and which will be published in a short time. It is sufficient for me now to state that more than once I have seen a cavy die from an intraperitoneal injection of 5 cubic centimeters of a determined serum, while another cavy, as heavy as the former, resisted 10 cubic centimeters of the same serum.

That the poison circulating in the blood of epileptics is the epileptogenous agent that all authors admit as the proximate cause of the disease, is, I think, probable, and it is doubtless always present in the blood of an epileptic.

Another objection to our explanation of the crises of accommodation is this: If the said toxic principle does represent the epileptogenous agent commonly circulating in the organism of epileptics, how can we explain the fact that, by increasing it artificially through injections with very small doses of serum, severe perturbations arise in the stable equilibrium of the epileptic organism with phenomena of acute intoxication?

I cannot answer so complicated a question, but I think these acute phenomena are to be ascribed to the quantity of the toxic principles rather than to their quality.

The individual state of a normal person must correspond to some peculiar bio-chemical condition of the tissues and humors of the economy. Individual variations must also exist in the bio-chemical constitution of the tissues and the humors of individuals in a pathological state. I will incidentally recall that the phenomena of an acute intoxication were induced directly only by injecting into one epileptic the serum of another epileptic. We never observed symptoms of acute and direct intoxication from injecting into an epileptic the same blood-serum he had supplied a few days before.

This fact shows that the toxic principles circulating in a free state in the different epileptics and having a common property (the power of stimulating the epileptogenous nervous centers) may have remarkable variations in their constitution. It is evident that it is easier for the organism of an epileptic to accommodate itself to its own toxin, than to a toxin fabricated in the organism of another epileptic. Therefore, it is not surprising that the injections with serum made into the individual from whom it was obtained provoke no inconveniences.

The second co-efficient, that is, the bio-chemical variations in the constitution of the toxin circulating in the different epileptics, must be taken into account to explain the diversity in the crises of accommodation caused by the injections with the serum of one epileptic into another epileptic.

Even if we have now demonstrated that in the blood of epileptics there is a toxin having direct importance to the etiology of epilepsy, we have not yet explained the genesis and nature of the active principles of epileptic serum itself, in spite of the analogy existing between these active principles and the antitoxic substances of modern serotherapy.

We have already seen that the restoring therapeutic properties of epileptic serum are to be ascribed neither to immunizing toxic substances nor to antitoxic ones. The analogy between the antitoxins of microbic serum and the active principles of epileptic serum are really only apparent. The existence of a toxin in the blood of epileptics might lead one to think of a relation of cause and effect between such a toxin and the active therapeutic principles. We know, of course, that such antitoxic principles of a biologic nature exist in the organism of animals to which the action of a vaccinating microbic substance has given immunity.

But in order that I may better demonstrate that a substantial difference exists in the genesis and nature of the antitoxins of microbic serum and those of the therapeutic principles contained in epileptic serum, I will call attention to the different mechanism in the elaboration of these two active principles.

First, the active substances of the serum of epileptics are formed in an organism, which, in opposition to that in which the antitoxic substances of microbic serum are fabricated, has no immunity. In the second place a toxin of endogenous origin, such as circulates in the blood of an epileptic, does not possess the inoculating properties of bacterial toxin.

The first proposition is demonstrated by the clinical course of epilepsy. The second, which can hardly be separated in the mind from the first, was demonstrated by our experiments.

If we wish to find an analogy between antitoxins in general and the therapeutic principles of epileptic serum, we must assume that the epileptogenous agent elaborates an antitoxin in a biological sense, which does not have any vaccinating properties. This will remain merely an hypothesis until demonstrated by experimental pathology.

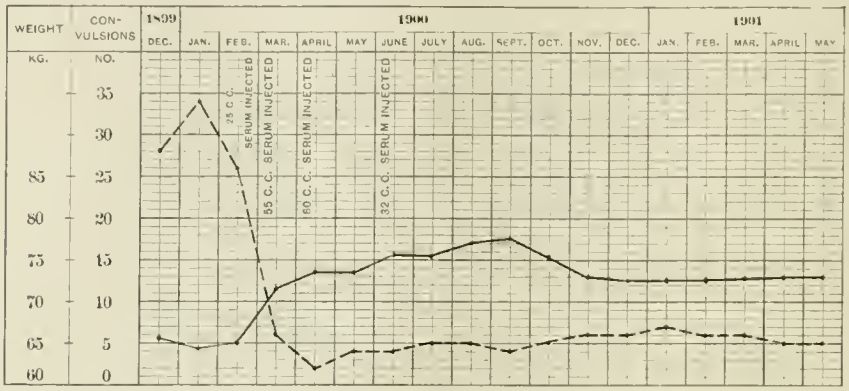
I will recall on this subject the discouraging results of the great researches by Bouchard. Bouchard, assuming that the peculiar secretions of a pathogenic microbe or organic cell are to be found in the urine and blood-serum of patients, tried to establish resistance through the one and the other to the bacterial (pneumonitis, erysipelas, etc.) and the non-bacterial (Addison's disease, etc.) diseases. It might be assumed that in epilepsy, also, it was a question of physiological principles existing in the tissues and humors of the economy, such as have, for the therapeutic action they exert, given rise to the transfusion of normal blood or serum, artificial serum, or the extracts of different organs (thymus, testicles, thyroid, etc.). But we have already seen that the blood-serum of normal individuals is almost always inactive in epileptics; therefore, we must exclude the idea of an active principle of mere physiologic origin. We have but to think of the transitory effect that may be determined by the physiological principles in general, as Gramatschikoff's studies have stated, to convince ourselves that the active principles existing in the blood-serum of epileptics must be of a different origin and nature. For the effects of the latter, especially the positive ones, exhibit a character of remarkable stability.

Any opinion as to the intimate nature of the active

principles existing in the blood-serum of epileptics would now be premature; therefore, I content myself with having stated certain facts and having tried to put them in evidence, with a detail that may serve to demonstrate their scientific and practical importance.

is different in different individuals. The phenomena it determines are transitory in character.

The other active principle circulates in the blood of epileptics, but only in a latent state. It is endowed with properties which have a stimulating power on the



Case V.

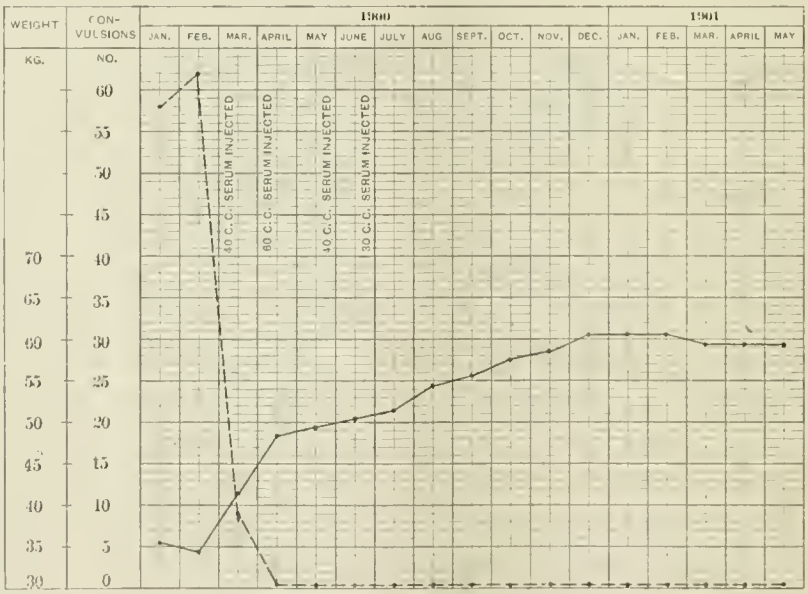
I hope that others may soon confirm my results and extend the experiments to less severely afflicted epileptics than these in the asylum to which I was obliged to limit my researches.

. . . . . .

We may then conclude by saying that the said researches demonstrate that in epileptic blood there are

metabolic cells which are concerned with the elaboration of the epileptogenous toxic agents.

These stimulating properties appear only as remote consequences that take place as a result of repeated injections over a considerable period of time with the blood-serum of an epileptic into himself or into another epileptic.



Case VI.

two active principles, which their different and opposite properties show to be of different nature and origin.

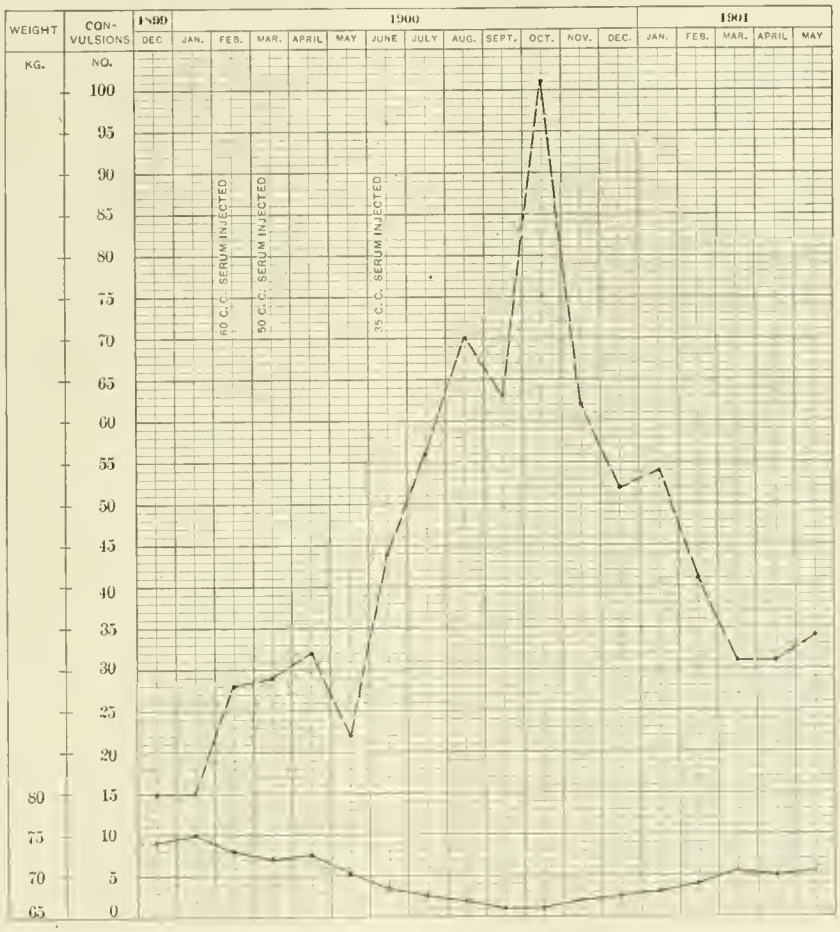
One of these principles circulates in a free state, and is only endowed with toxic properties when injected into the organism of another epileptic. The toxic effects may be immediate and direct and may follow even small doses. The activity of this toxic principle

These stimulating principles can deeply modify nutrition and epileptic manifestations. Upon both they exert a slow progressive action which may be restoring and therapeutic, or weakening and poisonous.

Their diverse and opposite modes of action depend upon some peculiar organic condition of the individual injected and are practically unexplained. The organic

condition of the patient in whom they are elaborated has no apparent influence on the different and opposite activities they may present.

In the cases in which stimulating principles have restoring therapeutic properties, there always result a remarkable increase in body-weight and an improvement or total disappearance of disturbances of organic functions or of social life. The disturbances of psychic functions and the epileptic manifestations of whatever nature get much better or disappear entirely. The stability of these positive results is in a direct relation with the degree of physiological reaction in the elements of nutrition.



Case VII.

In the cases in which the said principles do not act favorably on metabolism, the serum injections are useless. If continued in the same manner as in the preceding cases, there result a diminution in weight and a getting worse of every disturbance of the organic or social life. The psychic functions become more impaired and the epileptic manifestations increase in number and intensity, sometimes to a marked degree.

The accompanying tables are the graphic demonstrations of the changes in weight and in epileptic crises in Cases V., VI., and VII., as a result of the continued injections of serum.

In Case V. giddinesses and convulsions are considered together as epileptic accidents.

ORIGINAL ARTICLES.

ACUTE INFLUENZAL NEPHRITIS IN CHILDHOOD.

BY B. K. RACHFORD, M.D.,
OF CINCINNATI, O.;
PROFESSOR OF PEDIATRICS IN THE MEDICAL COLLEGE OF OHIO.

Experience leads me to believe that acute nephritis occurs not infrequently as a manifestation of influenza in children. Freeman[1] has reported a case of this kind and has collected and tabulated nine others.

In this paper I report four distinct cases of acute influenzal nephritis, which I have seen in the last few years. In addition to these cases I can distinctly recall two others not here reported, one of which was discovered on the fourth day of the influenza, and died of acute hemorrhagic nephritis two days later. The other was treated for a few weeks last winter, at the Good Samaritan Hospital, where I utilized the case in my clinical lectures. Under protest this patient was removed by his mother from the Hospital,

[1] Transactions of Amer. Ped. Soc., Vol. XII, 1900.

long before his convalescence was established. He was then treated for five or six weeks at my out-door clinic, under bad hygienic and dietary conditions, yet his recovery was complete.

Each of these cases occurred, not as a sequel but as a part of the influenza attack. The kidney symptoms in every instance occurred while other active influenza symptoms were still present.

The influenza poison attacked the kidneys and produced a most violent acute nephritis just as it, in other cases, attacks and produces inflammation of the lungs, the intestines, the meninges, and other parts of the body.

Acute influenzal nephritis as it occurred in these children comes on more quickly and violently than nephritis produced by scarlatina, diphtheria and the other acute infections. And my experience with these cases also teaches me that the worst symptoms occur as a rule within six or seven days after the kidney is attacked, and that, if complete suppression and profound uremia do not destroy the life of the child within the first week of the disease, a sure and steady improvement begins which leads to complete recovery. It is possible that in some of these cases, a chronic nephritis may be established, but I have never seen such a case. One of my cases previously referred to but not here reported, which, after the first severe symptoms had subsided, was treated in the out-patient department at my college clinic, certainly was given an opportunity to develop chronic nephritis by bad hygienic surroundings and improper food, and yet recovered. This case to my mind forcibly illustrates the strong tendency which there is to spontaneous recovery in these cases after the acute symptoms have been relieved.

These remarks apply only to influenzal nephritis as it occurs in infants and young children. In the adult the picture of this disease is a very different one, as is shown by Dr. G. Baumgarten in "Renal Affections Following Influenza."[1]

In the adult acute hemorrhagic nephritis, occurring during the influenza attack, is nothing like as common as it is in the child. Chronic nephritis, however, resulting from repeated attacks of influenza is much more common in the adult than in the child. Personally, I have never observed a case of this kind under twelve years of age.

From my own experience, in the following cases, I have been led to consider acute influenzal nephritis in childhood not as a sequel or a complication, but as a part of the influenza attack. The kidneys are among the organs of the body which are not exempt from primary attack by the influenza poison.

Case I.—Girl, seven years of age, has had in the last four years two or three attacks each of influenza and catarrhal croup and follicular tonsillitis. In March, 1898, she had an attack of laryngeal diphtheria, during which she wore an intubation tube for one week, and received 6,000 units of antitoxin. Her recovery was satisfactory and there was no evidence of nephritis at this time.

March 22, 1900, I was called to see this patient and learned that she had been ill with influenza for ten days. In the beginning of "the cold," the mother had kept her in bed for two days, but for the last week she had been going about the house and out of doors as she pleased. During this time she had had a bad cough and a "head cold," but not enough to alarm the mother, who had treated the case with home remedies. It was after dark when I reached the house. My patient was sleeping very soundly, but was awakened without much difficulty. She had a slight bronchitis, a catarrhal sore throat, and a temperature of 102° F. A puffiness about the eyelids led me to suspect nephritis and I accordingly prescribed calomel, a milk diet, and confinement to bed. I asked that a specimen of urine be sent to me next morning, as soon as it could be collected.

Two ounces of bloody urine were sent to my office about ten o'clock the next morning. This I learned later was all she had passed since the evening before. It contained blood and epithelial casts and was very heavy with albumin.

A trained nurse went on duty at five p.m., and I saw the patient a little later. Twenty-four hours had produced a marked change in my patient. The stupor was now marked, the face was swollen, and the stomach was so irritable that nothing had been retained during the day. Temperature 100° F. Calomel was continued and nourishment was discontinued.

March 23d, 8 a.m.: Symptoms unchanged; nothing has been retained on the stomach. No urine has been passed. The calomel was continued, a high rectal injection of a quart of sulphate of magnesia solution was given, and hot baths were ordered every four hours.

I saw the patient frequently during the day, and her condition remained unchanged. She slept constantly, except when vomiting, or when she was disturbed by a bath, or otherwise. No urine had been saved, and the nurse reported at 10 p.m. that none had been passed in the last twenty-four hours. It may be, however, that some urine escaped with the high enema of sulphate of magnesia solution which was repeated at 6 p.m. without effect. Magnesia sulphate was ordered by the mouth.

March 24th: Nurse has saved four ounces of bloody urine; the condition remains much the same, except that there was little less irritability of the stomach and the bowels had moved slightly. Sulphate of magnesia was continued, a teaspoonful every four hours, hot baths were continued, and high enemata of normal salt solution were ordered every four hours. No nourishment was attempted. At 8 p.m. the stomach was less irritable, quite a good deal of the magnesia had been retained, bowels had moved slightly, and about 3 ounces of urine had been collected by the

[1]Transactions Assn. Amer. Phys., Vol. X.

nurse. Treatment was continued. Dr. F. Forchheimer saw the case with me during the afternoon.

March 25th, 8 a.m.: Patient's bowels moved slightly during the night, stupor not so marked, stomach less irritable; 6 ounces of urine saved: 8 p.m., patient very weak, but otherwise improved, bowels have moved freely, and there has been no vomiting during the day; 4 ounces of urine saved. Treatment continued, except that the magnesia was given every twelve hours, and a little buttermilk was allowed during the night.

March 26th: Patient more comfortable this morning, but very weak, pulse rapid, and temperature one degree below normal. From this time on the patient slowly convalesced, but required careful attention throughout the whole month of April. During all of this time she was kept in bed and upon an exclusive diet of milk. The urine gradually cleared, but still contained albumin and casts until the middle of May. A trace of albumin was found in the urine on the 18th of May. This was the last. Her recovery, although slow, was complete and by the middle of June she had recovered her health and strength and has remained well up to the present time.

Case II.—Albert A., twelve years of age; all the members of his family including himself had influenza. I stopped at the house on March 1, 1897, to see his brother and sister. He, while he had "a cold in his head," was not considered ill enough to require the services of a doctor. I did not visit the family for a week after this date and during this time my patient had fever, cough and other influenza symptoms. About the 6th of March, however, he was thought well enough to visit a friend in another part of the city. He remained there during the day; his father came for him in the afternoon, and found him very nervous and suffering from a frightful headache. He ordered a carriage to take the boy home and drove past my office in doing so. The boy walked into the office with his father, and as I was not there they decided to wait for my return. One-half hour later, about 5 p.m., he had a very severe general convulsion, and a number of physicians in the neighborhood were called to see him. On my return at 6 p.m. I found him lying on a lounge in a heavy stupor, from which he could be aroused with difficulty. I assisted the father in carrying the boy into the carriage and he was taken home. On our arrival there I obtained some urine by catheterization and found it heavy with albumin, and containing many granular and epithelial casts. This made the diagnosis of influenzal nephritis plain. He was ordered sulphate of magnesia, a teaspoonful every two hours, and a hot bath every three hours. During the night he had another violent convulsion. The next morning the stupor was a little less marked and the swelling of the face which had existed the night before was also very pronounced. The magnesium had been retained and his bowels had moved freely. During the next few days, the hot baths and magnesium sulphate were continued and a small amount of milk was given. From this time his convalescence was rapid; at the end of three weeks the albuminuria had entirely disappeared, and the patient was convalescent.

Case III.—Girl, seven years of age, was admitted to the Children's Ward of the Cincinnati Hospital December 2, 1900, with influenza, which she had had for one week. At the time of her admission the tonsils were swollen and red and the cervical lympathatics were enlarged and tender. Temperature 102° F. There was no history of any other acute infectious disease. Physical examination showed slight bronchitis with some swelling about both ankles. A specimen of urine obtained by catheterization contained about 4 per cent. by volume of albumin; epithelial casts were present; specific gravity, 1024.

Treatment consisted in rest in bed, milk diet, calomel, and hot baths every six hours.

December 3d: Patient retained very little milk, vomiting occurred a number of times. No urine was passed voluntarily after the catheterization twenty hours ago. Eight and a half ounces of urine were obtained by catheterization. Sulphate of magnesium, a teaspoonful every four hours, was added to the treatment.

December 4th: Stomach less irritable, bowels moved freely, some urine has been passed voluntarily. Sulphate of magnesium given once a day; baths every eight hours.

December 5th: Patient improved, milk is retained, edema less, bowels moved freely, urine passed voluntarily, albumin less.

December 15th: Patient has improved steadily, there is no albumin in the urine to-day.

January 3d: Patient discharged well.

Case IV.—Boy, four years of age. He and three other brothers and sisters had had influenza for a week, and during this time he had a mild bronchitis, a catarrhal sore throat, and a nasal catarrh, with a temperature ranging between 101° and 104° F. After one week's illness, on February 1st, he was seized with a convulsion and brought to the Cincinnati Hospital, where I saw him for the first time. The convulsions continued for more than two hours, and during this time the convulsive movements were partially controlled by inhalations of chloroform; hot baths and chloral by the rectum were also given. The convulsions, however, continued, and after a few hours it was decided to dispense with the chloroform and give a twelfth of a grain of morphine hypodermatically. The morphine controlled the convulsion, but the child remained profoundly unconscious. On his admission to the hospital a small quantity of urine was drawn from the bladder, this urine was tinged with blood, and the filtered urine contained a very large percentage of albumin. Epithelial and blood casts were abundant. The examination of the urine led to the diagnosis of acute nephritis, and the treatment above detailed was accordingly pursued.

Following the hypodermic injection of morphine, salt solution was given by the rectum and

also subcutaneously, and the hot baths were continued at frequent intervals. But these means failed to establish the kidney secretion; the patient remained profoundly unconscious and died the next day. In this case the hypodermic injection of morphine should have been followed by bleeding and the intravenous injection of salt solution.

A NEW METHOD OF LOCATING FOREIGN BODIES BY MEANS OF THE X-RAY.

BY LEWIS GREGORY COLE, M.D.,
OF NEW YORK.

Various methods of locating foreign bodies have been described; some simple ones without the use of expensive apparatus; others more complicated and requiring such apparatus. Of the simpler methods the one most in vogue is that of taking two skiagraphs at right angles to each other. This is applicable only when the foreign body is in an extremity and even then, unless the technic be perfect, there is a chance for error. (1) The skiagraphs should be taken at right angles to each other. (2) The tube should be at the same distance from the plate during each exposure. (3) The rays which cause the shadow of the foreign body should strike the plate at right angles. (4) The anode should be directly over the approximate location of the foreign body as ascertained by a fluoroscopic examination.

After having taken two skiagraphs, one to locate the foreign body anteroposteriorly, the other to locate it laterally, estimate the third dimension by its relation to some bony prominence. Measure the distance on the skiagraph from the foreign body to some bony prominence and then measure the same distance on the extremity from that bony prominence in the direction of the foreign body and mark the point with silver nitrate.

This seems accurate, but how often the needle, bullet or whatever it may be, appears to have moved since the skiagraph was taken! I think the following diagram will explain the error in this method.

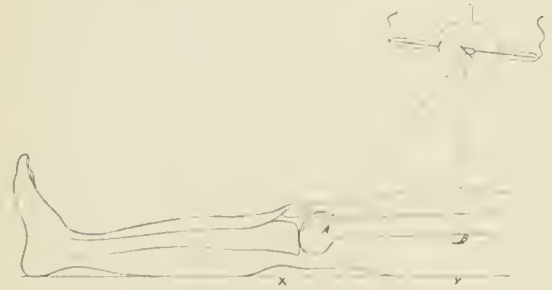


Fig. 1. X, shadow cast by adductor tubercle; Y, shadow cast by foreign body; A, adductor tubercle; B, foreign body.

If the tube be over the foreign body, located about the middle third of the thigh, a ray of light falling perpendicularly casts a shadow of that foreign body under it. Selecting the adductor tubercle on the inner tuberosity as the nearest bony prominence, a ray of light passed through it does not fall perpendicularly on the plate, but at an angle corresponding with the distance of the tube from the plate, and the distance of the foreign body from the adductor tubercle and the distance of that bony prominence from the plate, which in an adult is about three inches. Therefore the shadow cast by it on the plate is further from the shadow cast by the foreign body than the latter is from the bony prominence.

Now if we measure the distance in the skiagraph between the foreign body and the adductor tubercle, and then measure the same distance up the thigh from that bony prominence and mark it with silver nitrate, we shall find that that mark is as much above the foreign body as the shadow cast by the adductor tubercle on the plate was below that bony prominence.

Another simple method consists in taking two skiagraphs on separate plates at different angles; then measuring the distance from the edge of each plate to the shadow cast on it by the foreign body and subtracting the one from the other.

There is much difficulty in substituting the second plate for the first one. The movement of the patient and the movement of the plate in the envelope lead to an error that is hard to overcome. Even if the technic were perfect, there would be nothing to guide the operator as to where to make an incision, as the shadows cast by the bones are so distorted in each of the skiagraphs, owing to the angle at which the rays of light fall on the plate, that it would be very misleading, as shown by the diagram of a foreign body in the thigh.

Another method, that of taking two skiagraphs on one plate by interposing a metal plate so as to cover one-half of the plate while exposing the other half, has been described. The interposing of metal so as to protect one-half of the plate without interfering with the shadow cast by the foreign body on the other half is extremely difficult, especially when the foreign body is near the posterior surface of the body, and its shadows are cast near together; it is absolutely unnecessary, though if one does succeed in getting both shadows on one plate in this method, one has the foundation for locating the exact distance of the foreign body from the surface; but no way of locating it as regards its relation with any bony prominences because of the error described in locating the foreign body in the thigh or with any known point on the surface of the body.

I would like to present the following method, which does not require expensive apparatus, which is applicable to any part of the body—especially the thorax and abdomen, and which is, I think, absolutely accurate both as regards the location of the foreign body and its distance from the surface, and which gives the operator a definite problem, viz., The foreign body is between two known points on the surface of the body; how far is it from either of these two points?

To ascertain the first, remove the patient's clothing and place him horizontally on a table through which a fluoroscopic examination may be made.

Place the tube over the region of the foreign body and make fluoroscopic examination. This may or may not result in its approximate location. If it does, leave the tube placed directly over it. If not, a skiagraph may be taken to ascertain this, and then place the tube over the approximate location as ascertained by skiagraph.

If the fluoroscopic examination reveal the foreign body, place two coins (dimes), one on the anterior, the other on the posterior aspect of the body, so that a ray of light passing vertically from the anode would pass through both coins and the foreign body—thereby all casting one shadow on the fluoroscope or plate. Remove the coins and mark their position with silver nitrate.

If the foreign body cannot be detected by a fluoroscopic examination and the coins are so arranged as to cast one shadow, the method is a little more difficult, but none the less accurate. Instead of arranging the coins during a fluoroscopic examination, we must do so by taking a skiagraph. Arrange the coins as before, so that they both cast the same shadow as near as possible to the approximate location of the foreign body as ascertained by the first skiagraph; then take a second skiagraph and learn the relation of the foreign body to the coins.

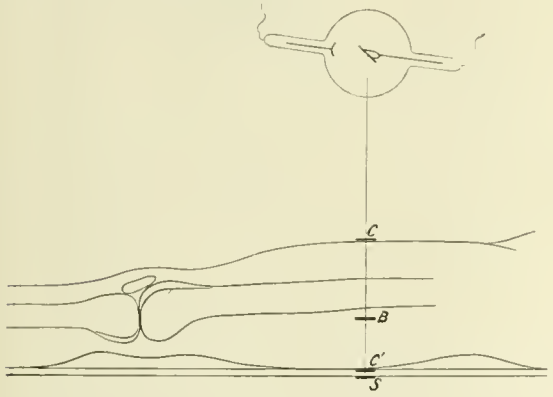

Fig. 2. C and C', coins; S, shadow cast by coins and foreign body; B, foreign body.

If the foreign body be between the coins, it will cast its shadow with theirs; if it be *near* an imaginary line passing between the coins, it will cast its shadow *near* theirs. Measure the distance between the shadows cast by the coins and that cast by the foreign body, move the coins this distance in the direction of the foreign body. If it be less than an inch, remove the coins and mark their position with silver nitrate; if more than an inch, it is safer to take another skiagraph and ascertain whether the foreign body is between the coins. We now know, either from the fluoroscopic examination or the skiagraph, that the foreign body is between two known points marked with silver nitrate.

To ascertain how far the foreign body is from the surface, place the plate in apposition to the body at the posterior mark, then place the anode directly above the anterior mark. If one has been able to detect the foreign body and arrange the coins during a fluoroscopic examination, the tube will already be there; if not, drop a plumb line from the anode to the anterior silver nitrate mark. Note the distance of the anode from the plate.

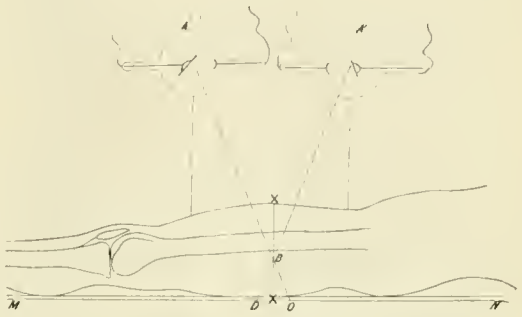

Fig. 3. A, tube in first exposure; A', tube in second exposure; O, shadow cast by bullet during first exposure; D, shadow cast by bullet during second exposure; B, foreign body; M, N, plate.

On this plate make two exposures, moving the tube for the first exposure a short distance from its present position. For the second exposure move it exactly the same distance from its original position but in the opposite direction. Note this distance. This may be done by marking on the surface of the body two points equally distant from the original silver nitrate mark and in directly opposite directions, using a plumb line to place the anode over these marks, as per diagram.

Now one has two shadows of the foreign body on one plate; develop the plate regardless of everything except these two shadows. Using the distance between them, one can ascertain by the following diagram and formula the distance of the foreign body from the surface:

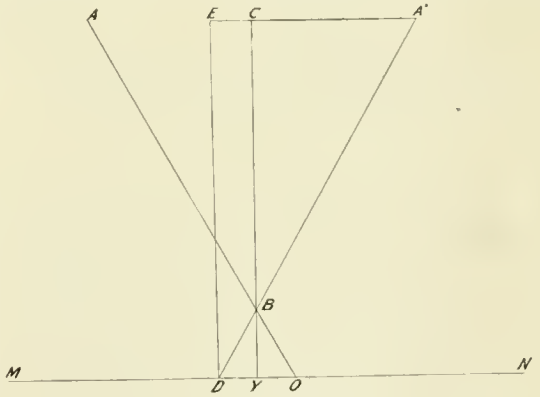

Fig. 4. Diagram.

Let MN be the plate; B. the bullet; A, the position of tube during first exposure; A', position of tube during second exposure; O, shadow of bullet first exposure; D, shadow of bullet second exposure; CY, a fine passing perpendicularly through bullet.

If the distance CY is 14 inches, if the distance AA' is 6 inches, if the distance DO is 1 inch, in order to find the distance BY, draw line ED parallel to CY; then in the similar triangles, A'ED

and A'CB, A'E : A'C :: ED : CB; or, substituting measurements, 3½ : 3 :: 14 : X, X=12. If CB=12, then BY=2 inches. Therefore the foreign body is two inches from the surface of the body.

A simpler method of calculating is as follows: AA' + DO : AA' :: CY : CB; 7 : 6 :: 14 : X.

CY=14 inches.
CB=12 "

BY= 2 " from surface of the body.

The skiagraph of an adult who was shot in the shoulder, the bullet entering just at the greater tuberosity of the humerus, was taken. There were a hematoma, pain and tenderness of the subcoracoid space.

I took a skiagraph from behind forward which showed the bullet about 1¼" from the head of the humerus toward the median line.

A resection of the shoulder was decided on and it showed that the bullet had passed obliquely backward and inward; an incision into the subcoracoid space showed the hematoma to be from injury to the head of the humerus, and that the bullet was posterior to the chest.

I then took another skiagraph making two exposures on the same plate, with the tube in the second exposure six inches from its position during the first, and placing the angle of the safety pin at the position of the posterior silver nitrate mark. The tube being 13 inches from the plate, working it out from the above formula, I found the bullet to be 3.1 inches from the posterior silver nitrate mark. As the man was very thick through the shoulders and chest, that would bring it between the scapula and chest-wall instead of in the subcoracoid space, as the first skiagraph would lead one to think.

THE RATE OF GROWTH OF EPITHELIUM OF ULCERS; OBSERVATION OF 100 CASES AT THE VANDERBILT CLINIC, N. Y.

BY SIGMUND DEUTSCH, M.D.,
OF NEW YORK.

The following experiments were made in order to ascertain with some accuracy the rapidity with which new epithelium will grow over ulcers or raw wounds, and to deduce from the results obtained the best method or methods by which ulcers of various varieties can be healed in a relatively short time; in other words, the employment of such means as will produce a sufficient stimulation to the epithelium surrounding the ulcer and to the ulcer itself.

In order to obtain satisfactory results, it was necessary to watch the ulcers, each individually, measure their extent, record the treatment and the results thereof, and observe whether they yielded to treatment. To this end, the ulcers under observation were measured every week and by this means one could readily see if any progress was made.

There are also other factors which to a certain extent influence the results obtained and must necessarily be taken in consideration. The cause of an ulcer; its situation; the condition in which the ulcer is found, whether it presents a healthy, and clean or a sloughy or gangrenous surface or a foul discharge; whether superficial or deep; and, lastly, the age of the patient. The season of the year plays perhaps some rôle, since hot weather is detrimental to varicose and eczematous ulcers, but has little influence upon the other varieties.

With regard to the cause, I have found it very convenient to divide ulcers into three classes: (1) Those belonging to the varicose and eczematous variety; (2) those due to constitutional or local syphilis; and (3) ulcers due to trauma, including burns, infected wounds and ulcers due to vaccination.

The situation of an ulcer is very important, not as a matter of diagnosis, but as a matter of fact. Ulcers situated at the malleoli, heel or arch of the foot are the most sluggish and most difficult to treat; while an ulcer situated on the arm will heal more quickly than one on the leg.

The condition in which an ulcer is found will alter the treatment and consequently the results obtained, for it makes a great deal of difference whether an ulcer is clean to start with, or whether weeks have to be spent in cleaning a sloughy or gangrenous area of ulceration. A discharging ulcer presents the same difficulty, though it requires less time to check this secretion.

The depth of an ulcer presents perhaps the greatest obstacle to its healing. If an ulcer is superficial, the structures lying beneath the epithelium are intact and abundantly supplied with blood-vessels; hence it will take less time for the epithelium to grow over this ulcer. But the case is quite different when the deeper structures are destroyed, not only because the ulcer is deprived of its blood-supply, but also because a very large quantity of material is required to fill the cavity. Therefore, a superficial ulcer measuring 25 x 35 mm. is really smaller than an ulcer measuring 10 x 10 mm. and perhaps 2 or 3 mm. deep.

The age of the patient must also be taken into account. In the old the blood-supply is less and the resisting powers are weak; and if in addition the state of nutrition is bad, one can readily see that an important stimulus essential to the healing of any wound is wanting.

Hot weather is certainly an impediment to the growth of the epithelium of a varicose ulcer, since it increases itching and the patient will surely scratch the affected part, thereby producing a great deal of irritation. The secretion is also increased and being easily decomposed is another source of irritation. Be it as it may, this much is certain—during the hot spell in July of last year I observed that nearly all the ulcers of the varicose and eczematous variety either became larger in extent or remained stationary for two or three weeks.

The treatment was manifold. Each case was treated on its own merit. Some ulcers responded readily to one remedial agent, while in others of the same variety no results whatsoever were ob-

tained. The varicose and eczematous ulcers constituted the majority of all the cases under observation (sixty-seven); therefore, I will speak of them first. The remedial agents in order of their importance were as follows: Balsam of Peru, red wash, creolin, silver nitrate, ichthyol ointment, lycopodium.

Balsam of Peru.—This is perhaps a stimulant most frequently used, though not always advantageously; for it must be remembered that it is often more irritating than stimulating. Therefore, it often happens that after a single application the ulcer is found in a worse condition than it was before, to say nothing of the pain caused the patient. Hence, whenever an ulcer is surrounded by an area of inflammation, as is often the case, and when this area is tender and painful to the touch, balsam of Peru should be abandoned and one of the milder stimulants employed. Some ulcers will remain indifferent to the application of balsam. They do not tend to become worse, neither do they show any improvement. However, a great many cases were treated with this agent, and it is beyond doubt that balsam of Peru is a valuable stimulant in appropriate cases. The measurement showed that the ulcers treated with it decreased on an average from two or three and one-half mm. per week.

Red Wash.—This is a much milder stimulant than balsam of Peru, and possesses one advantage over it, in that it is not irritating, and is therefore particularly adapted to those ulcers surrounded by an area of inflammation. But if an ulcer is found to be indolent and of long standing, other means must be resorted to. It is especially beneficial for traumatic ulcers and raw wounds, and can be used when there is any objection to iodoform.

Creolin.—This is perhaps the most efficient drug for gangrenous or sloughy ulcers. It is somewhat irritating and causes itching, but its advantages outweigh its disadvantages. As long as an ulcer presents an area of gangrenous matter with a most offensive odor, a stimulant

would be out of place and nothing would be accomplished by it. The first step is to remove all the slough; creolin accomplishes this most admirably, and at the same time time disinfects the wound. A solution of ½ per cent. strength should be used, 1 per cent. in more advanced cases. The ulcer being cleaned, one can proceed to apply stimulants.

Silver Nitrate.—The silver nitrate stick was employed with the intention of stimulating the edges of the ulcer and thereby causing a growth of new epithelium. In some cases the end sought was obtained, but in a greater number of cases the effort was futile, even when the ulcer itself was touched with the stick. This procedure, being somewhat painful, should be abandoned as soon as it becomes evident that the ulcer fails to decrease in size.

Ichthyol Ointment.—This may be compared to balsam of Peru, being both stimulating and irritating. Though it may benefit some ulcers, it produces a most intense itching, not observed when applied to sound skin. It does not present any advantages over the other stimulants. Its main use was application in a combination with zinc oxide or boric-acid ointment to the inflamed or tender skin surrounding the ulcer.

Lycopodium.—If an ulcer is accompanied by a wet eczema, or if the ulcer itself discharges a foul secretion, a stimulant would not only be out of place, but might tend to produce a true dermatitis with exacerbations of the ulcer itself. An ointment would tend to block the secretion while not diminishing it. Hence, a bland drying-powder is indicated. Lycopodium or any other non-irritating drying-powder can be used. It will certainly not heal the ulcer and that is not to be expected, but it may dry up the wet eczema. I found in lycopodium a valuable agent for this purpose. Boric-acid powder produces itching and is consequently irritating.

Syphilitic Ulcers.—The second class of ulcers are either due to constitutional or local syphilis. They are not so persistent as those of the preceding variety and are not so painful. The statement that syphilitic ulcers will heal by themselves if internal treatment is administered is not quite correct. Without local treatment a syphilitic ulcer will, in the majority of cases, tend to spread and to destroy the deeper structures. One may apply either the blue ointment or the red wash and creolin. The application of a saturated solution of alum acetate will give excellent results and should be made often, especially if a discharge is present. A few applications of this solution removed discharge and slough, leaving a clean and healthy wound, and the complete closure of the ulcer will then be a matter of two or three weeks.

Traumatic Ulcers.—Under this heading all those ulcers are included which are caused by some injury, be it a kick or a blow, fall, burns, wounds healing by second intention, and vaccination ulcers. The most frequent site of the traumatic ulcers under observation was the anterior surface of the leg; next in frequency was the elbow; and a few occurred at some other part of the body.

A traumatic ulcer on the anterior surface of the leg, particularly if caused by a kick or a fall, will heal very slowly; stimulation is of no avail save in exceptional cases. The healing qualities of alum acetate as observed in syphilitic ulcers are almost wholly absent here. (This fact is, perhaps, of some importance for the diagnosis of ulcers the cause of which is uncertain. If such a traumatic ulcer responds readily to the treatment of alum acetate it is very probable that this ulcer is of syphilitic origin.)

As a matter of choice one may apply either the boric-acid ointment or ichthyol ointment; or if stimulation is desired, red wash, creolin or balsam of Peru. Sometimes the application of the silver nitrate stick will eventually hasten the closure of the wound. If a traumatic ulcer is suppurating, the application of ointments should be abandoned and a wet dressing applied. With regard to vaccination ulcers, the application of a wet dressing or boric-acid ointment will answer best.

Summary.—The observation of these cases has shown that (1) the rate of the growth of epithelium is in direct proportion to the size of the ulcer; (2) in the majority of cases the average growth of epithelium is from two to three and one-half mm. per week; the range is 1.4 to 10.5 mm. (traumatic ulcers not included); (3) the time required to heal an ulcer is in no proportion to the duration of the ulcer; an ulcer of four months' standing does not heal quicker than one of four years' standing, other conditions being equal; (4) the rate of growth of epithelium in traumatic ulcers is extremely irregular; it is in no relation to the size or duration of the ulcer; the average growth per week is about five mm.; the range is from 1.4 to 8 mm.

I wish to express my most sincere thanks to Dr. E. M. Foote, chief of the surgical clinic, for supplying me with the necessary cases, and to the clinical staff for their kind assistance.

MEDICAL PROGRESS.

OBSTETRICS AND GYNECOLOGY.

Treatment of Inversion of Uterus.—The treatment of early cases is sufficiently well understood. The treatment of chronic cases, in which the cervix has contracted and involution is completed and in which adhesions have formed within the funnel of the inverted uterus, is not so easy to determine. Constant elastic pressure may be successful if used early and faithfully; but there remain inveterate cases which demand surgical relief. Three procedures are applicable: (1) The method of Thomas, in which the abdomen is opened, the funnel dilated and the uterus replaced; (2) the method of Kuestner, which reaches the funnel through an opening from the vagina into the cul-de-sac of Douglas; (3) vaginal amputations of the uterus. The weight of surgical authority, according to E. W. Cushing (Boston Med. & Surg. Jour., Feb. 13, 1902) seems to be against the operation of Thomas. Although previously content with vaginal hysterectomy in these cases, Cushing decided after reconsidering to

adopt Thomas' method in a case which came to him for treatment, for the following reasons: The method had never been tried since the introduction of the Trendelenburg position, which posture will presumably be of as much advantage in treating inversion abdominally as in performing hysterectomy. Adhesions can be separated more carefully from above. The ligaments which support the uterus will be found elongated and weakened, and ventrofixation will avert recurrence of the inversion. Less blood will be lost if all manipulation be done from above. The whole operation will be cleaner. On these *a priori* grounds, Cushing treated his case by the method of Thomas, and his experience was in entire conformity with his anticipations. The position of Trendelenburg being used, Thomas' operation becomes the operation of election, being easier, safer, cleaner and more surgical and satisfactory than any other.

Vesicovaginal Fistula.—A new method of operating in this condition, with the report of a case, is described by A. L. Smith (Phil. Med. Jour., Feb. 15, 1902). The patient presented a tear of the bladder, vagina, and cervix, about two inches long, extending from back of the spincter vesicæ down through the os. The steps in the operation are briefly as follows: After incision of the vagina in front of the cervix, the bladder was pushed back from the uterus, the laceration of the cervix being repaired by Emmet's trachelorrhaphy. The fistula was then cut at the junction of the bladder and vagina. The tear in the bladder was sewed up with catgut (chromicized), the muscular wall only being included, this forming a strong ridge. The vaginal slit was closed with interrupted sutures of silkwormgut, passing through the vagina, then through the muscular wall of the bladder about half an inch to one side of the tear and out on the other side of the vagina, thus displacing the bladder to one side so that the two suture lines did not come together. The advantages claimed are as follows: (1) No stitches are left in the mucous membrane as foci for calculi; (2) instead of a narrow edge for union in the bladder, a thick ridge is secured, and (3) the lines of suture in the bladder and in the vagina are not approximated, a stronger result thus being obtained.

Abdominal and Vaginal Celiotomy.—No unchangeable laws governing the choice between these two methods of operating can possibly be laid down, but the general principles are expressed as follows by H. MacNaughton-Jones (Med. Press & Cir., Jan. 22, 1902). In the abdominal method there is a better field of view, greater command over the affected organs, fuller power of exact dealing with the ovaries and tubes in carrying out conservative measures and in breaking up extensive adhesions. Knowledge of the size of cysts, sacs or solid growths greatly facilitates their treatment. There are, however, cases in which the vaginal route is the operation of selection. In simple parovarian cysts and small cystic tumors of the ovaries, in cases of cystic disease of the adnexa, complicating small interstitial myomata and subperitoneal myomata in the cul-de-sac of Douglas, in adnexal trouble, complicating retrodeviation of the uterus—in short, in cases which are more or less recent, with movability and nonadhesion of the mass, with the uterus itself mobile—by Martin's operation of anterior colpotomy the uterus can readily be turned into the vagina and the adnexa removed if necessary. Should difficulty arise, the advantage of removing the mass in pieces by claw, forceps and scissors, by Doyen's drill, by slicing the uterus into fragments (Landau's method) can be resorted to. As a rule, however, the frequency of cancer and tuberculosis in this region makes it advisable not to follow this method oftener than is necessary. When in doubt the abdominal route is much the better. Conservatism in operating on the adnexa is always very important and is really the source of modern success.

Heart Disease in Pregnancy.—The mortality among women with cardiac disease who have become pregnant varies from 20 to 55 per cent. The condition, therefore, is one of the most grave and fatal of all those which confront the obstetrician. Prof. Webster (Medicine, Feb., 1902) has considered it in all of its phases, but with especial reference to the therapeutic indications. There are a number of factors, each of which must be individually appreciated, which serve to invalidate the heart in pregnancy. The enormous increase in the vascular area and in the total quantity of blood imposes an additional mechanical strain on that organ. The deterioration in the blood, anemia, etc., lead to malnutrition of its musculature and to a certain degree of paresis. The distention of the abdomen limits the oxygenating power of the lungs, impedes their auxiliary action in circulation, and blocks the pulmonary circulation. All cardiac cases, therefore, suffer to a greater or less degree during pregnancy. If hypertrophy of the heart be sufficient, the disturbances are slight, manifesting themselves only as palpitation, cough, dyspnea, and slight edema. In the cases which fail to compensate properly, the most serious symptoms may supervene. The woman may then succumb to heart disease during pregnancy, or abortion may occur. If the case goes on to labor, this may also prove fatal to the woman. The treatment of all cases of heart disease should be prophylactic in the early stages. If abortion threaten, or if signs of beginning cardiac insufficiency appear, but, especially, if these two conditions occur together, the physician should always be ready to end the pregnancy in the interest of the mother. The labor, whether premature or at full term, demands the most careful management. If the patient stand it well, she may be permitted to go through the first stage without interference. If signs of heart failure appear, she is to be chloroformed, and the cervix dilated with Barnes' bags or manually. The second stage presents similar indications. The woman is to be assisted, if necessary, by the forceps. The best stimulant during this stage is nitrite of amyl, or nitroglycerin, which neutralizes the increasing strain on the heart, due to the additional blood thrown out of the retracting uterus, by diverting it into the dilated abdominal vessels. The third stage is that most to be feared. Strangely enough, there is one set of observers which attribute the danger to anemia of the heart, while others hold that the patient dies from overdistention. The author belongs to the latter group: "The whole vascular area of the body has been greatly reduced by the contraction of the uterus; the extra strain on the right side of the heart may be too much for it;" overdistention and paralysis supervene. The indication is plain. The third stage is to be prolonged, at the cost of considerable loss of blood, in order to give the cardiovascular mechanism a chance to adapt itself to the altered conditions. The placenta is gradually separated by the fingers, and uterine contraction should be stimulated only if the loss of blood becomes extreme. During the puerperium, the treatment is limited to careful nursing, and symptomatic treatment.

Extra-uterine Pregnancy.—When a diagnosis of this condition is made soon after the rupture and before the patient has lost much blood, an operation should always be performed, but, unfortunately, the diagnosis is usually not certain till the patient has become so exsanguinated that any interference would probably result in death. J. W. Elliot (Med. Rec., Feb. 22, 1902) has operated successfully upon twenty such cases and is convinced that there is very little danger in waiting

a day or two for the patient to recover her strength, for he says it is very rare for them to bleed to death at the time of rupture. They almost always subsequently regain sufficient strength to warrant an operation and usually stand it very well. He believes, however, that if they are not operated upon, the chances of another hemorrhage are very great; it is almost certain to occur. In operating he finds the uterus as soon as possible and, after ligating both ends of the offending tube, rapidly removes it, leaving the blood clots in the abdomen to be absorbed. Any unnecessary delay or manipulation is hazardous.

Spontaneous Rupture of the Uterus.—Rupture of the uterus during pregnancy or parturition is, happily, a comparatively rare occurrence. The signs of threatened rupture are usually so clear that R. M. Murray (Jour. of Obst. & Gyn., Brit. Empire, Feb., 1902) thinks that its occurrence is a reproach to the obstetrician in whose hands the case is. The rupture is either traumatic or spontaneous. Under traumatic causes must be included all cases brought about by mechanical violence, such as the forcible introduction of the hand into the uterus, the unskilful performance of version, and the improper use of forceps, etc. These may be classified as internal traumatisms. External traumatism is a term to be applied to those cases of rupture due to blows on the abdomen and to falls. Spontaneous rupture has for its immediately determining cause the contraction of the uterus. The great majority of these cases are, however, associated with some condition arising from an abnormality of either of the two factors of labors—the "passage or the passenger." Examples of the first are found in cases of rigid os and contracted pelvis; of the latter, hydrocephalus or malpresentation. Thanks in the main to the classic work of Bandl, the mechanism by which the process occurs is known to all. With an obstruction to the dilatation of the os, the lower uterine segment becomes thinned out, while the muscular tissue of the upper segment gathers itself together into a sort of cap on the upper pole of the uterine mass. The strain on the lower uterine segment increases until it gives way, in most cases not far from the junction of the two segments. The tear tends to run across the long uterine axis. In contracted pelvis the location of the tear is determined by the grinding of some portion between the fetal head and the pelvis. On the other hand, spontaneous rupture may occur in certain cases without any process such as that described by Bandl. There may be no abnormal obstruction to the escape of the uterine contents; the labor may only have begun, and, moreover, the tear may have no special relation to the lower uterine segment, though it may, by extension involve it, too. Three sets of cases may be found in this group, viz.: (1) Interstitial pregnancy rupturing at the fifth or sixth month, even following the first labor pain. (2) Spontaneous labor following abnormal conditions, such as bicornate uterus, myomata uteri, and a uterus which has previously been the subject of a Cesarian section. (3) A small number of cases have been reported in which rupture took place at the beginning of labor in a uterus of normal conformation, and in which there was no gross complication. Cases of this sort have been recorded by Ingersler, Hofmeier and Simpson. The first two failed to show any histological reason for the accident. Simpson's case showed signs of fatty degeneration of a marked degree.

Carcinoma and Pregnancy.—Pregnancy complicated with cancer of the cervix is unfortunately much more common than is generally supposed, says J. E. Gemmell (Jour. of Obst. & Gyn., Brit. Empire, Feb., 1902). Solowij estimated that it occurred once in two thousand labors; in most instances it is demonstrated in the earlier months of pregnancy and ends in abortion or is treated at once. In early cases it is the generally-accepted view that the uterus and its contents should be removed as a whole with as little delay as possible by vaginal hysterectomy; this is quite feasible up to four or four and a half months, and has been performed at the sixth month. The author finds in looking over the literature that pregnancy and puerperium favor the growth of the neoplasm, hence early operation is advised. This is more serious in the later months. Natural labor permits the introduction of other septic infections and the bruising of the tissues. After the uterus has been emptied, it must be removed as soon as possible, as involution and absorption favor the spread of carcinoma and the production of metastases (Olshausen). The best operative results have followed radical operation by the vaginal route. Whatever the treatment, the results are unsatisfactory. The choice of the route depends upon the surgeon and the individual case. Abdominal hysterectomy, with removal of the os *per vaginam*, is preferable to panhysterectomy. The methods of operation are: (1) Cesarian section and hysterectomy by abdominal route (Freund); (2) Cesarian section followed by supravaginal hysterectomy, suture of abdominal parietes, and extirpation of the cervix *per vaginam* (Zweifel); (3) Cesarian section, suture of the uterus and abdomen and then vaginal hysterectomy (Olshausen); (4) Cesarian section and total hysterectomy *per vaginam* (Dührssen); (5) panhysterectomy and the extraction of the child after removal of the uterus (Bland-Sutton).

Cesarian Section under Local Anesthesia.—A most interesting case of this variety is reported by H. R. Spencer (Jour. of Obst. & Gyn., Brit. Empire, Jan., 1902). The patient was twenty-seven years old, a dwarf, and had a conjugata vera of 2½ inches. Twice previously this operation had been performed under general anesthesia. Before operation, Schleich's eucaine solution was injected along the line of the previous scars for about six inches. The scar was then incised for about four inches and the incision enlarged with scissors. The child was delivered in one minute and fifteen seconds; the placenta and membranes were removed in two minutes and thirty seconds from the commencement of the operation. The uterus and abdominal wall were then sutured in the usual way. The whole operation took twenty-five minutes till the dressing was applied. The first portion of the operation (incision and delivery) was practically painless; the sewing up of the wound in the uterus was also quite painless, but there was a good deal of pain in the sewing up of the abdominal wound, especially in stitching the fascia. The mother made quite an uneventful recovery; the child weighed 6 lbs. 13 oz., was vigorous at birth and has remained so. The author does not advise this method of performing Cesarian section, especially if the patient has "nerves."

PATHOLOGY AND BACTERIOLOGY.

Vital Blood-Staining.—As the result of their experiments in staining living blood-cells by various agents, Rosin and Bibergeil (Deut. med. Woch., Jan. 23, 1902) find a corroboration of the theory that living tissues do not take up stains for which those declining in vitality show a marked affinity. It may be possible to attain in this way a differentiation by means of various stains of the degree of the loss of vitality which any tissue has undergone, as the authors believe they have shown in healthy human blood. In comparison with unstained specimens they desire to call attention to the convulsive amœboid movements of the leucocytes in staining with eosin and other acid stains, to the peculiar variation in the action of the methylene-blue

on the white blood-cells and the differential staining of blood-plates by this means; also to numerous variations in the staining of the granules and chromatin network of the nuclei by different anilin dyes.

Preservation of Secretions.—A simple method of preservation of specimens for purposes of clinical microscopical diagnosis is recommended by R. Rohnstein (Fortschritte d. Med., Jan. 15, 1902). It applies particularly to the various bodily excretions and its principles depend on thorough sedimentation with consequent displacement of the supernatant albuminous fluid by a solution with fixing and preserving properties and at the same time free from albumin. Its formula reads: Formol, 20 c.c., glycerin, 125 c.c., distilled water, ad 200 c.c. Thes pecial application for urine is as follows: The specimen is allowed to stand for from twelve to twenty-four hours in a conical glass with a small quantity of thymol added. The fluid is siphoned off and the sediment again washed with a like quantity of distilled water and allowed to settle for another day. This dissolves all the albumin. When the liquid is poured off, a 2-per-cent. solution of formalin is added, in amount about two or three times the quantity of the sediment, shaken, and the mixture allowed to settle. About half is then poured off and the same quantity of the preservative mentioned is added. With appropriate modifications, stomach-contents, sputum, feces, and exudates can be thus treated; the method has the advantage of obviating all actual handling of the material, and does not cause any morphological changes in the tissue or cellular elements.

Diabetes Mellitus.—The pathogenesis of diabetes mellitus is still unknown, but it is probable that there are several pathological conditions which may cause the disease. C. E. Nammack (Med. Rec., Feb. 15, 1902) reviews the various theories which have been advanced. The principal ones relate to a perverted glycogenic function of the liver cells, to perverted metabolism in the tissues generally, to alterations in the pancreas, and to trophic disturbances. There are two liver theories, one that the liver cells are unable to convert the sugar into glycogen and the other that the cells cannot hold the glycogen after it is formed but allow it to be transformed too rapidly into sugar. The perverted-metabolism theory supposes an inability on the part of the muscles, glands, and other glycogen savings-banks to appropriate the sugar which is brought to them in the blood. Since 1877, when Lancereaux called attention to the pancreas, various lesions of this organ have been found in etiological relation to the disease, but in some cases extensive distruction of the gland has failed to cause diabetes and the simple diversion of the secretion from the intestine also results in no glycosuria. It is, therefore, supposed that the pancreas secretes into the blood some glycolytic ferment necessary for the proper conversion of sugar into glycogen. Besides mentioning the various alimentary toxic and traumatic glycosurias, the author believes that the strenuous life which is being led at the present time acts as an important factor in inducing the disease, and, although very difficult to prove, it is probable that trophic nervous disturbances are responsible for many cases of diabetes.

Effect of Liquid Air on Pathogenic Bacteria.—This subject has been taken up experimentally by C. M. Belli (La Riforma Medica, Jan. 25, 1902). Extreme cold, produced by evaporation of liquid air, not only prevented multiplication of germs, but decreased their number, the least resistant forms succumbing to its influence. To determine the possibility of bactericidal properties inherent in liquid air, cultures were directly exposed to its action by suspension in a vessel containing it. Inoculation of animals with cultures so treated showed that liquid air does not destroy the vitality of the more virulent bacteria.

Bacteriology of Scarlet Fever.—That there is some important connection between scarlatina and the streptococci, hitherto found in many of its lesions, has been confidently asserted by many investigators. Baginsky and Sommerfeld (Archiv für Kind., Jan., 1902) report the constant finding of streptococci in the tissues and blood of scarlatinal cases. In no one of the many cases investigated at necropsy were the streptococci absent from the cardiac blood and the bone-marrow. Cultures taken from the membrane of patients with scarlatinal angina showed streptococci, admixed with pneumococci, leptothrix, etc.; in only five per cent. of the cases were they associated with the Klebs-Löffler bacillus. As to their morphology, which is of a distinctive character, the streptococci form chains of varying length. The single coccus is round, but frequently is flattened at right angles to the axis of the chain; examined closely it often resembles a diplococcus, but its morphology is subject to considerable variation. When subjected to the action of blood taken from patients convalescing from scarlatina, these streptococci failed in every instance to give the agglutination reaction.

Soaps of Lime and Magnesia in Urine.—Crystals of this sediment resemble those of tyrosin, but are larger and the spicules are more tapering. G. E. Pfahler (N. Y. Med. Jour., Feb. 15, 1902) reports three cases in which these crystals were found, but suggests no significance attached to their presence, except, perhaps, their relation to certain toxic influences. In one case the crystals were obtained during an outbreak of acute mania, but were not present at other times. The second case was one of abscess of the liver, and the third was one of cocaine-poisoning. They have also been reported in the feebly-acid urine of a case of puerperal septicemia.

The Suprarenals and Their Active Principle.—In a lengthy article H. Singer (Therap. Monatshft., Jan. and Feb., 1902) discusses our present knowledge of the suprarenal bodies. Much has been done in recent years to bring the importance of these organs into the foreground, but the question as to what their true function is still remains unanswered. The rich nerve-supply, derived from the celiac ganglion and suprarenal plexus, has been frequently commented upon. It is interesting to note that the organs are more highly developed in negroes and less so in anomalous conditions of the central nervous system, such as hemicephaly and anencephaly. Other anatomical peculiarities are the rapidity of circulation in the organs, so that the venous blood frequently is arterial in appearance, and the occasional presence of accessory adrenals. The adrenals themselves are of relatively large size in the embryo and the active principle, which is capable of producing a green color with ferric chloride and which raises blood-pressure, is already secreted during the second half of gestation. Electrical stimulation of the cortex is without effect; faradic irritation of the medulla leads to local contraction of the renal vessels and diminished diuresis. Removal of both organs is always fatal except in animals, like the eel, which have no medullary substance, and in man any disease leading to their destruction is followed by Addison's disease, except sometimes in carcinoma, when it seems as if the cancer cells could continue the function of the normal organ. When one side only is extirpated, a compensatory hypertrophy of the remaining gland takes place. The question as to whether transplantation of foreign suprarenal tissue can save life is not definitely settled. The most prominent symptoms caused by even minute doses of the ex-

tract of the medullary part of the organ are local anemia and considerable but transient increase in blood-pressure, while the pulse is first accelerated and then slowed. Large doses are followed by a marked lowering of blood-pressure, arhythmical pulsus bigeminus and, finally, stoppage of heart-action; excessive doses cause sudden and rapid cardiac paralysis with strongly-dilated right ventricle and with empty left ventricle. Respiration is increased with prolongation of expiration, later slowed with ultimate stoppage in expiration. The other symptoms are of less importance, pareses, diminished and later increased diuresis, etc. The search for the true active principle has been diligent. Besides albuminous principles in the form of globulins, lecithin, inosit, xanthin, leucin and neurin in combination with glycerophosphoric acid have been found. The substance affecting the blood-pressure is soluble in water, dilute alcohol, glycerin and weak mineral acids, but insoluble in ether and chloroform, and its isolation seems to be fraught with difficulties owing to its labile nature. A characteristic reaction is found in its behavior with ferric chloride, which gives a green color, turning rose on the addition of alkalies or free halogens. Though pyrocatechin gives a similar reaction there are many points of difference which make it clear that the two are not identical. Two substances have recently been isolated—suprarenin and epinephrin, but the results obtained with them do not make it appear probable that they represent the full activity of the gland. They are, however, recommended in diseases of the eyes and nose and as hemostatics.

Mast-Cells.—The fact that those cells with large basophile granules found in chronic inflammatory processes and similar ones occurring in the blood are not identical is pointed out by L. Michaelis (Münch. med. Woch., Feb. 11, 1902), who regrets that the name mast-cells is applied indifferently to both. A peculiar property of the granules of the mast-cells, which was long overlooked, is their solubility in water which is least marked in those normally found in the blood, but much more so in the cells of myelogenous leucemia, so that no aqueous and especially no alkaline dye can be used to identify them, even if previous fixation were perfect. The following method gives the best result: Fix the smears by means of alcohol or heat; stain for a few minutes in a saturated solution of thionin in 50 per cent. alcohol; wash in 50 per cent. alcohol; dry and mount in Canada balsam. The granules will then appear reddish-brown and the nuclei blue. In order to demonstrate the cells in tissues, embedding in paraffin or celloidin must be avoided; the tissues, after they are hardened in alcohol, are cut with a razor, stained, passed through alcohol and mounted in the usual way. The labile nature of the granules is thought to be a sign of their unripeness. In another article in the same journal A. Wolff states that he has been able, by means of these methods, to demonstrate mast-cells in tuberculous pleural exudate, which proves their power of active emigration.

SURGERY.

Joint Conditions.—The results of good treatment are nowhere in the body more apparent to the patient than in joints, for the self-evident reason that such outcome is associated with his power of self-support. R. L. Swan (Medical Press & Circular, Jan. 29, 1902) speaks emphatically against temporizing with tuberculosis of the joints and advocates prompt operation. He has had several cases do well under this treatment with complete or nearly complete recovery of total function. In his original operation he opened the joint freely by cutting across the patella, making first a flap on the skin, convex upward. The patella in young subjects is usually rather easily divided with a knife, when the whole of the interior of the joint comes widely into view. The synovial membrane is usually found congested and its branches edematous. He irrigates the joint for a considerable time with saline solution, removes every particle of loose, flocculent material, dries off the surfaces, applies pure carbolic acid with a swab, and again irrigates very freely as before. The joint is then closed, the patella having been sutured with catgut and the skin with silkwormgut without drain. A plaster-of-Paris bandage is then applied over the dressing. In thirteen subsequent cases he has modified this procedure as follows, with equal success and without as much damage to the joint. The incision is made convex backward, reaching from the lower part of the inner edge of the ligamentum patellæ to a point (in the adult) about two inches above the base of the patella. After the bleeding has been arrested the joint is laid open. In closing the wound three layers require adaptation and suture. First, the synovial membrane, second, a muscle layer, consisting of aponeurosis below, and aponeurosis and muscle above. He has not except in one or two cases used any drains, which he does not consider necessary if the wound is dried and rendered thoroughly aseptic before closing. Analogous to tuberculosis of the knee-joint is the same disease in the bursa, which lies beneath the ligamentum patellæ, where it makes an indolent swelling, slowly increasing and obliterating the hollows which naturally exist on either side of that ligament and occasionally reaching such great dimensions as to interfere with the use of the limb to a marked degree. The chances of the knee-joint itself becoming involved in the presence of such a bursitis are, of course, very great. The need of prompt operative interference in this condition is therefore manifest.

Foreign Body in the Esophagus.—The frequency with which this condition appears in childhood renders knowledge of every case as it appears in literature advisable. C. Peacock (Lancet, Feb. 1, 1902) reports the following interesting example. On December 21, 1901, a six-year-old boy was admitted to the Miller Hospital, suffering from a brassy cough, regurgitation of food and fever. The history showed that in July, 1901, the child had swallowed a ha'penny piece. Vomiting occurred immediately, but was not repeated. For the next three weeks the patient said that he could "taste the ha'penny," complained of pain under the chin whenever he took food, but at the end of that time these symptoms disappeared until December, when the patient again had trouble. At the beginning of December a dry, clanging cough, difficulty in swallowing and in breathing, and a regurgitation of food appeared and as the symptoms steadily grew worse he was brought to the hospital for treatment. Examination by the X-ray showed a coin caught in the esophagus at the level of the third rib, with the flat surfaces facing anteriorly and posteriorly. On January 1st, the patient was anesthetized and an attempt was made to remove the coin with a coin catcher. As this effort failed the probang was tried and at the second effort the coin was found in the pharynx. It was black in color and entirely covered on one surface with inflammatory exudation. Immediately after removal of the coin the patient's breathing became easy and his recovery was rapid. Feeding by the rectum was at first thought advisable, but owing to his age was not successful. Mouth feeding was then cautiously begun and after two days was increased in quantity at each meal. At the end of the week he was allowed to have solid food. His recovery was complete, there being no sequela whatever in evidence.

Pathological and Clinical Significance of Abdominal Pain.—In most acute abdominal lesions pain is

the earliest, the most persistent, and the most significant sign. When hemorrhage is the only lesion, pain is the expression of violence done to the peritoneum. The commonest cause, says M. H. Richardson (Boston Med. & Surg. Jour., Feb. 20, 1902), is the rupture of an extra-uterine pregnancy. The pain is often knife-like and paroxysmal; it is felt low down in the pelvis and is excruciating. Such a pain, occurring in women of childbearing age, should suggest ruptured ectopic gestation. If there be the least sign of hemorrhage and the least confirmatory sign of pregnancy, the abdomen should be opened immediately. When, after ovariotomy, the pedicle slips out of the ligature and the patient bleeds to death, there is as a rule no pain; when an extra-uterine sac bursts the pain is excruciating. In both cases there is simple abdominal hemorrhage without sepsis; the difference is in the pain. The pain of acute pancreatic disease is not sufficiently distinctive to differentiate it from the pain of other epigastric lesions. In rupture of the liver, spleen or kidney, pain is at times insignificant and at other times prominent. The severe pain of initial violence, increased by hemorrhage, gradually subsides as the signs of hemorrhage become marked. The diagnosis in traumatic cases must depend on signs of hemorrhage following a violent blow, rather than upon the character of the pain. The pain of ovarian torsion is that of a suddenly enlarging and sensitive ovarian tumor—hemorrhage, with its familiar signs, sometimes augmenting the shock of ovarian torsion. In the hemorrhage of gastric or duodenal ulcers pain is not present unless there be perforation into the peritoneal cavity. The pain of abdominal lesions dependent upon rapid and extensive extravasations of septic material, is sudden, sharp and overwhelming. It is at first continuous and violent, then paroxysmal and intermittent or dull and continuous; at first localized, it becomes generalized as the septic material spreads. In general peritonitis with excessive distention, pain usually subsides; it may disappear entirely when the general condition is hopeless. The pain of general peritonitis causes anxiety and shock. In no case of simple functional pain is there the effect upon the mind of grave apprehension or of constitutional shock upon the body. It is what precedes or accompanies pain, or, more often, what is conspicuous by its absence, that gives to pain its real significance. If, with overwhelming pain, there be rigidity of the abdominal muscles and general tenderness, and if the pulse be rapidly rising, immediate exploration is warranted. Rarely does the surgeon see such a combination with normal or subnormal temperature, for in an almost incredibly short time the temperature rises and distention, vomiting and obstipation develop. Large perforations of the bowel, appendix and stomach, all have the same course. The pain of appendicitis usually starts about the umbilicus or in the epigastrium, but soon after the onset it becomes localized in the vicinity of the appendix. In any variety of abdominal extravasation it is common for the pain to start at or about the umbilicus, or in the epigastrium, and to become localized in a short time near the seat of the lesion. A consideration of age, previous history, habit, etc., will lead the way to a differentiation of cholecystitis, gastric ulcer or pancreatitis, as the cause of acute, sudden epigastric pain.

Closure of Abdominal Incisions.—It is estimated that ten per cent. of all cases of laparotomy are followed by veneral hernia. I. S. Stone (N. Y. Med. Jour., Feb. 8, 1902) gives the following as the most frequent causes of herniæ: (1) Wound infection resulting in loss of fatty and connective tissue and consequent separation of wound surfaces; (2) improper wound coaptation or failure to unite corresponding layers; (3) enteroptosis with pendulous abdomen; (4) severe vomiting or straining before complete union. One very efficient factor in the causation of herniæ is the presence of long peritoneal flaps which have been more or less bruised during the operation. Their nutrition is poor and they may either be forced upward between the two wound surfaces or from their looseness may allow pocketing of serum and blood between them and the abdominal wall. He advises, therefore, the removal of all excess of peritoneal flaps and also of all loose or necrotic pieces of muscle or fat. Each layer should be closed separately with buried catgut, so that peritoneum, fascia and muscle layers meet corresponding ones on the opposite side. Through-and-through sutures are very effective, but should be passed in such a way that, while piercing the deep fat and muscle layers, they are at a considerable distance from the wound surface, coming out near the wound at the skin and peritoneum surfaces. Pressure is thus exerted upon the deep layers as much as upon the peritoneum and skin.

Stricture of Esophagus.—A case of complete stricture of the esophagus following the ingestion of concentrated lye is reported by H. M. Taylor (N. Y. Med. Jour., Feb. 8, 1902), who found that, after doing a gastrotomy and passing a bougie from above downward, the stricture was at least one inch in length and so dense that no opening could be found. The stricture was near the lower end of the esophagus so that external esophagotomy was impossible; a sharp-pointed bougie, carrying a piece of silk, was finally forced through. The Abbe saw-string method was then employed until a larger bougie could be used. The patient was fed through a gastrostomy wound and the dilated and inflamed esophagus was allowed to heal. When the inflammation had subsided the child could easily swallow a little liquid food and by gradual dilatation a good-sized opening was soon produced in spite of the fact that the passage of bougies had been unable to prevent the original closure of the esophagus. He advises earlier operations in such cases, in order that the esophagus may be allowed to rest and that food be taken through a gastrostomy wound to prevent extreme wasting. Systematic passage of bougies should be continued for years, if not for life.

Circular Incision in the Operative Treatment of Varicose Veins and Ulcers.—The circular incision is warmly recommended by C. Weizel (Berl. klin. Woch., Feb. 10, 1902), who has operated according to this method in 22 cases of varicose veins and ulcers of the lower extremity. In every case, so far as Wenzel has been able to ascertain, cure was permanent. Some of the cases had resisted other methods of treatment for long periods of time. As a rule, the incision is made at the juncture of the lower and middle thirds of the thigh; the vessels and recognizable cutaneous nerves are avoided. The veins are then divided one by one and the upper and lower cutaneous margins are approximated by a running suture. No drainage is required. In cases of ulcus cruris the greatest caution must be exercised to prevent infection of the operative wound. If possible, a dressing should be applied to the ulcerating area and left in place at least until the time of removal of the stitches and, if possible, until the circular incision has entirely healed.

Tuberculous Peritonitis.—The results of operation upon 28 cases of tuberculous peritonitis are reported by Bottomley (Amer. Med., Feb. 15, 1902) from the Boston City Hospital. The operation consists typically in opening the peritoneal cavity, evacuating the fluid, and closing the wound. In view of the fact that the uterine

adnexa furnish the point of origin of the disease in 25 per cent. of the cases, the question of the advisability of their removal is very important. If the peritoneum covering these organs be affected only as part of the general miliary peritonitis, there is no good reason for disturbing them. If, however, there be tuberculous salpingitis or oöphoritis, and if removal be not too difficult, they should be taken out. As regards omental masses and enlarged glands, the outcome of these 28 cases shows that they ordinarily cease to give trouble after simple laparotomy and need not be dealt with separately. Fibrous bands, which threaten intestinal obstructions, are to be divided. Drainage not only is of no benefit, but is apt to lead to permanent sinuses and fecal fistulæ. The immediate result of the operation is almost always an improvement, at least in the general condition. There is a diminution of the pain and of the distention and a fall of temperature. Of the 28 cases, 11 were cured, *i. e.,* were free from symptoms of the disease one year after operation; two were improved; four could not be traced; 11 died in from one to four months after operation. Thus, a cure may be reasonably expected in from 30 to 40 per cent. of all cases. According to most authorities, operation is attended by the best results in the ascitic form of the disease; in this series, operation on the fibrous variety gave equally good results. The prognosis in the ulcerative form is always bad.

Surgery of the Pancreas.—Five years ago it would have been impossible to give a detailed account of the surgical treatment for diseases of the pancreas. Such treatment simply did not exist. To-day, however, it has been possible for Roswell Park (Amer. Med., Feb. 15, 1902) to describe a well-planned procedure for each of the conditions which arise in connection with this organ, and for the various complications which present themselves during the course of an operation. There are five routes by which the organ may be approached: (1) Through the lesser omentum, above the stomach; (2) through the greater omentum, below the stomach; (3) through the transverse mesocolon; (4) through the liver, with a thermocautery, and (5) through the loin, retroperitoneally. The treatment of the various conditions is as follows: Acute traumata are to be treated on general principles, by checking hemorrhages, suturing all lesions of continuity and draining. The difficulty consists in diagnosing such injuries, on account of the depth of the organ and the obscurity of the initial symptoms. Park holds that if a wound be so placed as to make injury of the pancreas even probable, it is proper to make a high laparotomy and explore the organ through the gastrocolic omentum, without reference to the injury to other viscera. Drainage may be made anteriorly or posteriorly through the loin, or in both ways. The operative treatment of tumors is confined to such as occupy the splenic end; excision is of course indicated, although the necessary ligation of vessels may imperil the life of neighboring viscera. Cysts of the pancreas are peculiar by reason of the extremely dense adhesions which they contract. The rare pedunculated forms are to be extirpated. In most cases, the cyst is tapped with the trocar, sewed to the abdominal wall, and drained. There follows a very prolonged and tedious recovery. Pancreatic calculi are always to be sought for during the course of operations for cholelithiasis. If palpated, they may be expressed into the duodenum or removed by incision into the duct or gland. Acute pancreatitis has been divided into a number of types by pathologists. All of these forms, however, betray themselves by the same symptoms, namely, those of an acute epigastric peritonitis, and demand the treatment proper for that condition. The pancreas having been exposed by either the supra- or the infragastric route, all foreign matter, such as clot or pus is removed and necrotic portions of the gland are excised. Drainage should be made posteriorly. The treatment of subacute pancreatitis practically coincides with that just outlined. The treatment of chronic pancreatitis consists in locating and removing all calculi from the biliary and pancreatic ducts. Park closes this very brilliant review of the present aspect of the surgery of the pancreas with the admonition to operate early and promptly: "When in doubt, operate."

MEDICINE.

Intestinal Perforation by Ascaris.—The possibility of ascaris lumbricoides passing through the normal intestinal wall has been an open question; most clinicians holding that an intestinal lesion prepares the way for perforation. Of special interest, therefore, is S. Solieri's (La Riforma Medica, Jan. 31, 1902) case of fatal purulent peritonitis of sudden onset, in which operation revealed perforation of the intestinal parietes by the ascaris, the passage of a number of the latter through the puncture being visible at the time of operation. Microscopical examination showed entire absence of localized degeneration or inflammation.

Variola Hemorrhagica.—A case which is interesting because it appears to show that variola in intrauterine life had rendered the patient insusceptible to vaccination for fourteen years, but that after a period of eighteen years it had afforded no protection against a fresh attack, is reported by W. G. James (Lancet, Feb. 1, 1902). The patient, a governess, seen first on January 1, 1902, complained of chill, pain in the back, nausea, nasal and bronchial catarrh, cough, furring of the tongue, overdue menses, a temperature of 103° F. and pulse 108. She had been working harder than usual and felt worn out. January 6th, she suffered from backache so severe as to prevent sleep and ordinary turning in bed. Constipation was present, for which she had taken medicine. On the evening of January 7th, she was relieved of some of the pain and passed a good night. On the 8th her menses appeared, her fever and backache became less and she felt much better. That night, however, the menses became more profuse and offensive, and later an eruption appeared on the face. On the 10th the skin of the whole face was red, inflammed, swollen, covered with vesicles, giving the idea of uniform scalding. Scattered over the neck, trunk, arms and thighs, were numerous small vesicles with reddened bases, among which were a few larger vesicles with dark brown centers, of which only half a dozen were counted. The tongue was coated with a thick white fur and on the left of the palate was a vesicle of dark brown color, about one-sixth of an inch in diameter. The catamenial discharges remained profuse, foul in character, and she was expectorating blood-stained mucus. She was removed to the hospital in the evening, but the bleeding from the uterus and lungs increased. She died January 13th. On inquiry the following facts were elicited: Six months before this patient was born her mother had suffered from a severe attack of smallpox, from which, however, she made a good recovery. The patient was born at full term and showed a few smallpox pits. In infancy she had been vaccinated and revaccinated unsuccessfully. At nine years of age she was vaccinated and revaccinated unsuccessfully and again at fourteen years of age without result. With such an experience her parents naturally thought she was immune and unfortunately she was not vaccinated when smallpox broke out last year.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

CANCER RESEARCH.

Destructive criticism is the notion prevalent throughout the six-part report of the Harvard Cancer Commission, read last month before the Boston Society of Medical Sciences. The pathologists carrying on this work find it greatly easier at present to determine what does not occasion cancer than to offer supported suggestions as to what conditions do produce it; and not unnaturally.

By the aid of excellent lantern slides and many well-made drawings, four researches were summarized, work in each case lasting throughout the year since the last report was delivered. Coccidia, molluscum contagiosum, torulæ, and blastomycetes had been studied by as many experimenters and observers and each found to be unconnected with carcinoma, however surely productive these are of various pathological conditions more or less similar to cancer.

In this respect the report agrees closely with that of a year ago. Quite as conclusive in a way and not a little more interesting was the description of the attempts made to inoculate the various varieties of this tumor into some of the lower animals. All of these attempted infections proved practically negative, irritation being produced to a greater or less degree, but cancer apparently never—nor, indeed, anything very similar to it.

This is, immediately speaking, a not very encouraging consequence of these laborious, highly technical and scientific studies for it does not promise any proximate solution of this one of the most important problems of pathology, and does not therefore suggest even the outset of a step toward relieving the "poor race of men" from this wretched scourge. Still, indirectly, the tendency of this work is distinctly progressive, for even by the thoroughly scientific principle of exclusion alone, with specific positive discovery, we may at last be taught the nature and cause of the disease. If with the constant advances in the methods of preserving, of serially cutting, and especially of staining tissues, no sort of parasitic cause can be discovered in all these years of study by so many hands and eyes and brains, one might in all rationality at length be justified in shifting the responsibility of these mortal growths from parasite to host, and to a disordered protoplasmic metabolism of a mode as yet unguessed.

Our knowledge of the nature of protoplasm has developed faster and more substantially within the last three years than in as many previous decades, and it now becomes fairly probable that the normality of any tissue depends on the normal or average balance obtaining between the solid particles of the protoplasm and the liquid in which these particles are supposed to be in suspension. Whether or not this balance is an electrical tonus, as appears at least possible, or of some other nature matters little; the balance or equilibrium is certainly a delicate one, very easily disturbed, both on the instant and structurally for relatively long periods of time. We are, especially, only just beginning to realize how important are various inorganic salts in this protoplasmic equilibrium. While, then, the recent contention of the European observer that cancer depends on an excessive ingestion of sodium chloride may not be true, no one is at present prepared to say and to demonstrate that it may not be due to an excess or deficiency of any one or more of the several inorganic salts which all protoplasm contains and which are, in part, positively known to be essential to normal metabolism and function.

This second annual report of the Harvard Commission certainly strongly suggests some such solution to this problem: it implies, even more forcibly than before, that there may be some protoplasmic lack which, it may be, even the now

very fashionable *ions* may be induced before long, under the skilful guidance of some up-to-date young man, to supply! Back to the cellular protoplasm! is the present cry, for there perhaps not only the mysteries of the outgrown "vital force" of our grandsires, but assuredly of many of the more practical puzzles of physiology and of her sister, pathology, lie concealed. Of these mysteries cancer may be one—and the solution easier than to-day it seems.

PUBLIC URINALS.

Some days ago a citizen, a lowly and doubtless very ill-bred and indelicate citizen, while in the act of urinating against the spokes of his truck wheels was taken *"in flagante delictu,"* toted to court and fined five dollars.

It is a common sight to see boys of not too tender years marching with broad and straddling gait down our busy streets and avenues casting from them, with rare satisfaction, that stream of urine which the resilient bladder of youth alone can throw. With the advent of age, however, there is a change. The lad may empty his bladder in public with impunity; the man's less elastic organ must dilate—or do the other thing. Does it not seem reasonable that many pathological lesions—hypertrophied prostate among them—may be traced to this lack of public urinals?

Some one has said that the male sex has no longer any rights or privileges. This seems to be a good example of that concept. As New York now stands it is either burst your bladder or go to a grog-shop, where courtesy as well as custom demands that you buy a drink in exchange for the privilege granted you—of leaving one!

Throughout Southern Europe and in most of the cities of Germany, there is a urinal to be found in every single block. It is quite true that in Naples, for example, they are, to one not familiar with the sight, disgustingly public, but it's a case of "*Honi soit.*" The publicity arose from the fact that in former generations there were no women of the upper classes on the streets; the urinals have not been made more private, because even to this day but few of the high-caste women course the streets save in carriages.

Our arrangement, based on the conception that the act of urinating is a criminal one—this basis being produced by the self-same forces which forbid the proper regulation of prostitution—seems vastly inferior. If, in this matter the men have no privileges, how is it with women? By just the number of barrooms to which men may retire are they worse off than the men. England suffers from the same false modesty, urinals being as infrequent there as here. It is an Anglo-Saxon trait.

President Cantor's office is said to be a veritable municipal beehive, so busy is he with his great corps of aids in executing many plans for public improvement. Is there any question more trenchant, more gravely needing his care and efforts?

SMALLPOX AND VACCINATION.

Experience is our most inexorable and most faithful teacher, and no more so in any other sphere of knowledge than in that of public health. It is now a well-established fact that the world, especially perhaps the more civilized nations, within the last two years have been undergoing the worst epidemic of smallpox known for at least a generation. Of all countries in Europe probably none has suffered as much as England, where the "conscientious scruple clause" of the vaccination law has been the cause of many people avoiding this precaution. While this is true in Great Britain, in Germany smallpox in its typical form is almost an unknown disease, probably for no other reason than that vaccination is obligatory and the law is vigorously and consistently enforced.

All statistics are somewhat misleading, because their bare figures cannot express all the factors in a case like this and because too often in tabulating the figures various essential elements are either altogether omitted or not given their due weight. There have recently appeared, however, tables rather more valuable than usual concerning this matter of smallpox and vaccination in England. It is well here that we look them over carefully in order to gain and remember the lesson they emphatically teach. (A. Gubb, La Sem. Méd., 1902, No. 6). Historically the laxity in the vaccination law began in England in 1895 when the question of the ultimate value of vaccination was up in all its phases before the public in virtue of a committee of Parliament appointed to look into the question and formulate new laws. The objections against a fixed obligatory law were so numerous and persistent that Parliament was finally persuaded to pass a clause in the law by which a person having "conscientious scruples" against vaccination might avoid it by conforming with certain regulations. England was preceded in these tactics by one of the states of the Swiss Confederation, namely the Canton of Berne,

which in 1895 passed a similar regulation. The difference between a small community like this canton and a large and densely-populated country like Great Britain is at once apparent, but at the time did not carry probably as much weight as such a fact should.

Whatever the results in Switzerland have been, these are the present statistics as far as Great Britain is concerned, beginning with 1842, comprising therefore sixty years of the century just ended. The relative proportion of children less than five years old, of subjects between five and twenty years old, and of adults after the twentieth year who died of smallpox in London from 1842 to 1900 is the following: Adults older than twenty years of age perished only ten in a hundred from 1842 to 1850, eighteen between 1851 and 1860, twenty-six in the next decade, thirty-eight in the following, forty-six between 1881 and 1890, and, finally, fifty-four from 1891 to 1900. Persons between their fifth and twentieth years showed a variable curve, which in 1842 began with eighteen per cent. and in the decade of 1881 to 1890 reached twenty-six per cent., after irregular oscillations and since then has fallen to fourteen per cent. In young children less than five years of age, the value of vaccination was shown by a descending curve from sixty-eight per cent. in 1842 regularly and steadily to twenty-four per cent. in 1881. Since the relaxation of the vaccination laws it has risen steadily until in 1900 it reached thirty per cent.

The importance of knowing how many young children at the present time escape vaccination in England is shown by the curve taken from the records beginning in 1872 and ending in 1898. From 1872 to 1882 the curve slowly and irregularly sinks from eight to six per cent. From 1882 to 1892 it rises steadily from six to eighteen per cent. and thereafter rapidly and without breaks to thirty-three per cent. in 1898. It is therefore apparent that probably at the present time, with the disease causing ravages among infants, fully one-third are to-day not vaccinated by law in England.

If now we contemplate the death-rate of all subjects irrespective of age during the epidemic of 1901 in London we find the following: The curve for the non-vaccinated, less than a year old, begins at eighty-eight per cent. and slowly sinks to thirty-two per cent. for patients between the tenth and the fifteenth year. It then rises irregularly and steadily until ninety-eight per cent. is reached for the age between thirty and thirty-five, when an irregular descent occurs until no deaths are reported between the fiftieth and eightieth years, while for the vaccinated no deaths whatever were reported for subjects between a few months and ten years old. At fifteen years the deaths were about one-half of one per cent. For the age limit of thirty to thirty-five the rate was sixteen per cent. The highest range of mortality for the unvaccinated is a little less than twenty-eight per cent., ranging from that down to twenty per cent. and covering the period of life between thirty-five and seventy years of age. Thereafter no deaths were reported.

It will be seen from this comparison that the death-rate in the non-vaccinated is many times greater than in the vaccinated for all periods of life up to the sixtieth year. Thereafter, so far as this special epidemic was concerned, by causes not shown in the statistics more deaths occur in the vaccinated than in the non-vaccinated subjects Specific reasons for this certainly can be found, because they must exist in order to explain a variation from the law which so patently governs this disease in all the earlier periods of life. Hardly any one would need any further argument to convince him of the absolute value of this form of prevention against disease. There are other facts equally as convincing; for example, the experience of the German and French armies during the Franco-Prussian war. In the German army vaccination was compulsory. There were in it no epidemics of smallpox and a smaller number of cases practically than there were deaths from the disease in the French army, which had severe epidemics and at that time did not make vaccination compulsory. It therefore suffered from ravages of the disease throughout the war. Perhaps the painful experience of Great Britain and other civilized countries which have suffered more or less during the last two years from smallpox will at least show that in vaccination we have a means of protection that cannot be disregarded except at severe penalty and cost.

HELMHOLTZ AND SCIENTIFIC OBSERVATION.

ONE of the most promising signs in the medical literature of the opening century is the increased attention paid to the history of medicine. The story of the work of great observers and discoverers is not only informing in itself, but it is a source of inspiration to workers in similar fields. A more careful knowledge of the past of medicine would rid us of many claimants for long

anticipated discoveries and make the body of our medical literature less of a huge mass of endless repetition, often of things said much better by the older medical men.

Knowledge of the individual lives of great investigators would undoubtedly disclose the opportunities that lie open to all medical men for original observation. Genius is infinite patience, according to one great thinker, and the faculty for taking unlimited pains according to another. It may be that neither of these definitions exhausts the connotation of the word genius; it would seems that there is always something more—the divine spark that illuminates what has been obscure before; but there is no doubt that patient investigation has been the basis of all great discoveries.

The *Journal of the American Medical Association* devotes most of its pages of original matter in the issue of March 1st to papers with regard to Helmholtz, the semicentennial of whose discovery of the ophthalmoscope was celebrated at the last meeting of the Association. The sketches of his life and work show how much can be accomplished by the faculty for continued patient work, though spread over many things.

When Helmholtz began his professorial career, it was as professor of anatomy, physiology and pathology, at the University of Königsberg. This triple occupation, now usually divided among at least five professors, did not destroy his initiative. He was not one to be bound down by mere routine work. His physiological teaching suggested investigations in the transmission of nerve impulses and he proceeded to make them. But this did not satisfy his inquiring mind. From physiology he passed naturally to speculations on nerve tissue in its relation to psychology and thence to psychological problems. At this same time he was occupying his leisure time by observing through a telescope from the window of his room the methods of walking of his Königsberg fellow-citizens, in order to be able to write on the principles of human locomotion, a subject that had been made popular by Weber not long before.

This set of simultaneous investigations, at a time when he was not yet thirty years of age, forms a keynote to Helmholtz's life and character. Anything that was of interest to him, he followed up. He had what every great medical discoverer, Laennec, Schwann, Claude Bernard, Ramon y Cajal, has had, a manual dexterity that enabled him to construct instruments needed in his experimentation, the models of which did not then exist. He was what we call a "handy man," besides being an inventive genius. When he needed an electrical apparatus for his work in experimental physiology he made discoveries while engaged on the construction of the machine. His investigation of the physiology of the eye and the ear led him to the formation of great principles in optics and acoustics hitherto unknown or but partially realized.

Helmholtz is the type of man that must ever stand as a model for the race in the matter of scientific advance. No obscure question balked him. The unknown had an attraction because it inspired research. Mysteries have their approachable points, and once on the track patient observation and logical methods will surely accomplish results.

The lives of such men as Helmholtz must be better known and appreciated if the new century is to see great advances in the medical sciences, for new problems have become more complex, the more obvious discoveries have been made. Every years shows, however, that there are still promising fields for investigation lying invitingly open and that the capacity for taking pains in observation will have its adequate reward.

ECHOES AND NEWS.

NEW YORK.

Dr. Taylor's Book Translated into Italian.—An Italian translation of Dr. Robert W. Taylor's work on Genito-Urinary and Venereal Diseases has just appeared in Torino from the Union Typographical office.

Bellevue Alumni Association.—*Whereas*, In the death of Dr. Henry R. Baldwin, our Alumni Society has lost one of its most eminent and respected members, whose noble attributes and high professional character had endeared him to all his friends and to the community in which he lived; be it

Resolved, That we express to his family our deep sorrow and heartfelt sympathy in their sad bereavement; and be it further

Resolved, That a copy of this part of our proceedings be sent to the medical journals for publication.

Committee. { J. W. S. Gouley, M.D.
J. F. Erdmann, M.D.,
Irving S. Haynes, M.D.

Death of Dr. Munde.—The Medical Association of the Greater City of New York desires to give expression to the loss it has sustained in the death of its associate, Dr. Paul F. Mundé, one of its founders and most distinguished members.

In his professional life and work he exhibited the attributes of the conscientious and conservative physician, and, throughout his whole career, in every position he occupied, he discharged its duties with fidelity and devotion, winning the respect and esteem of all who knew him.

Our deepest sympathy is extended to his afflicted

family, and we hereby resolve that this vote be entered in our minutes and a copy be sent to the family.

Committee. { W. H. Katzenbach, M.D., Henry C. Coe, M.D., Chas. F. Adams, M.D.

Stony Wolde Sanatorium.—Mrs. Leslie Carter will appear at an entertainment to be given at the Buckingham Hotel on Tuesday, March 18th, in aid of the Stony Wolde Sanatorium Association. The entertainment will also enlist the services of other artists, among them Kyrle Bellew, Miss Marguerite Hall, Miss Fielding-Roeselle, Mrs. Robert Macpherson, Miss Amy Baker, the Hauser Quartet, and Bruno Huhn. Tea will be served at the completion of the programme.

New York Academy of Medicine.—A stated meeting will be held Thursday evening, March 20th. The following symposium on Operations for the Relief of Paralytic Deformities, with Special Reference to Tendon Transplantation, has been arranged. The papers will be as follows: Introduction; History; Indications for Operation, by Royal Whitman; Deformities due to Muscular Paralysis; Method of Production; Possibilities in Tendon-Transplantation; Combinations That Have Been Made to Correct Deformity, by Wisner R. Townsend; Technic of Operation; Results of Tendon Transplantation at the Hospital for Ruptured and Crippled, by Virgil P. Gibney; Neurological Questions Involved in Tendon Transplantation, by Joseph Collins.

Section on Ophthalmology.—Monday evening, March 17th: (I.) Presentation and Reports of Cases: (*a*) Case of a Free Cyst in the Anterior Chamber, by R. Denig. (*b*) Brief Report of an Epithelioma of the Eye-lid which disappeared entirely under the use of a solution of adrenalin chloride, by Wilbur B. Marple. (II.) Paper on Preventive and Hygienic Treatment of Myopia, by Alexander Duane. (III.) Paper: The Correction of Myopia by Glasses, by Walter E. Lambert. (IV.) Paper on Operative Treatment of High Myopia, by Peter A. Callan. (V.) Discussion by Drs. Bull, Gruening, Weeks and others.

Section on General Medicine.—Tuesday evening, March 18th: Symposium on Acute Articular Rheumatism. (I.) Paper on Remarks on the Pathogenesis, by Heinrich Stern. (II.) Paper on The Symptomatology and Diagnosis, by Leonard Weber. (III.) Paper on The Complications and Sequellæ, by Frank W. Jackson. (IV.) Paper on The Prognosis and Treatment, by W. H. Thomson. (V.) Discussion by Drs. Morris Manges, Edward G. Janeway, J. W. Brannan, S. Baruch, Abraham Mayer, Andrew H. Smith, Louis Fischer, R. Van Santvoord and others.

Section on Genito-Urinary Surgery.—Wednesday evening, March 19th: (I.) Presentation of Cases: A case of possible infection of syphilis from an instrument, in the person of a physician, by Frederick Griffith. (II.) Presentation of Specimens, Mulberry Vesical Calculus, by John Van der Poel. (III.) Presentation of Instruments: (*a*) Prostatic Douche Tube, by Ramon Guiteras; (*b*) Prostatic Cooler (Psychrophor), by John Van der Poel. (IV.) Paper on The Diagnosis of Renal Calculus, by Alexander B. Johnson.

Rochester Academy of Medicine.—The following program has been announced: Section III.—Obstetrics, Gynecology, and Pediatrics, Wednesday evening, March 19th. Paper: Hysteria and Insanity at the Change of Life, by Eugene H. Howard. Discussion on Hysteria opened by Edward B. Angell. Discussion on Insanity opened by Robert G. Cook.

Section IV.—Public Health, Including Hygiene, Climatology, Physiology, Pathology, Bacteriology, and Forensic Medicine, Wednesday evening, March 26th. Paper: The Prevention and Home Climatology of Pulmonary Tuberculosis, by William S. Ely. Discussion: The Bacteriology of Tuberculosis, by Charles W. Dodge; The Prevention of Tuberculosis by Early Diagnosis, by William L. Conklin; The Throat and Nose as Avenues of Infection, by John O. Roe; Infection through Cattle and Milk, by S. Case Jones; The Relation of Joint Tuberculosis to Pulmonary Tuberculosis, by Lewis W. Rose; The Pathology of Lympathic Tuberculosis, by Edward W. Mulligan; Why, if Ever, Do Skin Tuberculoses Remain Localized? by Dr. E. Wood Ruggles; The Influence of Tuberculous Patients on other Patients in a General Hospital, by Charles D. Young.

Presbyterian Hospital Loses.—Mrs. Annie Botsford, who sued the Presbyterian Hospital to recover $25,000 for having made, without her consent, an autopsy on the body of her husband, Albert Kent Botsford, recovered a verdict of $500 from a jury before Justice Gildersleeve in the Supreme Court yesterday.

Expert Medical Testimony.—Expert medical testimony was the topic of discussion at the one hundred and sixty-fifth regular meeting of the Society of Medical Jurisprudence, held last week in the Academy of Medicine. Dr. Graeme M. Hammond presented the paper of the evening. He deprecated the disrepute into which he said medical expert testimony had fallen and placed the blame both on the attorney and the physician. He disapproved of physicians acting, in litigations, in the dual rôle of medical counsel and expert witness, and said:

"In trials as they are conducted at present there is no possible chance for an agreement of experts. The witnesses for the two sides are not asked to give opinions based upon the same assumptions; each counsel has his own hypothetical questions, which differ from his opponent's as the night from the day. They are based upon absolutely different assumptions of facts, and the answers given are in accord with the assumptions in each question. Should the opposing counsel exchange hypothetical questions, the answer of every expert witness would be changed also.

"The expert opinions are of no value at all unless the assumptions contained in the hypothetical questions are proved to be true. If the jury believes the assumption in one hypothetical question the expert opinion based thereon is worthy of consideration; otherwise not. If these points were understood generally it would be seen that the seeming clashing of expert opinions is in reality nothing of the sort, but that the opinions given are merely what they claim to be, honest answers to absolutely different questions."

Dr. Hammond proposed as a remedy the selection of experts by each side, in litigations, who would examine the plaintiff or defendant in each other's presence and in the presence of a stenographer, who should note all that was said and done in the examination. This, he said, would do much to secure unanimity of expert opinion.

"When everything has been said, however," he continued, "it must be admitted that expert medical testimony, which should be a valued scientific and honored method of assisting justice to know the truth, has been prostituted by those attorneys who are willing to use any means to secure a verdict or save a client, and by those physicians who are willing to lend themselves for such a purpose. It is the medical expert himself who is to blame. When he recognizes the fact the remedy will quickly follow. The medical profession is respected everywhere but in the courts; let it be seen to that it is respected there."

State Lunacy Bill.—The Medical Association of the Greater City of New York at its meeting last week at the Academy of Medicine adopted unanimously and

without debate the following, addressed to Governor Odell: *Whereas,* Lunacy Bill No. 368, recently passed by the Legislature, has abolished the positions of the two Medical Superintendents at Ward's Island, New York, and has placed the two offices under one head, thus putting over 4,000 insane patients under one management; and

Whereas, A supplemental bill amending Bill No. 368 is now before the Legislature restoring these positions so that the division of the hospitals, as they formerly existed, one for men and one for women, may be maintained; therefore, be it

Resolved, That the Medical Association of the Greater City of New York heartily indorses this amendment and advocates its immediate passage.

For Compulsory Vaccination.—A bill amending the Public Health law was introduced in the Assembly March 6th by Assemblyman Fuller. It gives local boards of health the power to enforce general vaccination when required to do so by the State Commissioner of Health, who is authorized to make such a requirement for the protection of the public health.

PHILADELPHIA.

Decrease in Smallpox Cases.—During the week ending March 8th but 47 cases of smallpox were reported, this being the smallest number for any week since early last fall. The $225,000 appropriated for expenses attending the suppression of smallpox is now available and being disbursed. Of this amount $82,000 will be required to compensate the vaccine physicians employed by the city.

Post-Graduate Work at University.—The announcement has been made that the University of Pennsylvania will establish a spring school of medicine for practitioners. This movement has been contemplated for some time and will include courses of instruction in nearly all the departments of medicine. The regular faculty will have a prominent part in the teaching.

Women to Fight Expectoration Nuisance.—William H. Sims, station-master of the Broad Street Station, delivered an address on "Expectoration in Public Places and the Best Methods of Preventing It," at a meeting of the Woman's Sanitary League on March 3d. He discussed the subject mainly from the point of view of a railroad man, but said that the remedy was a law inflicting a penalty for expectoration in public places. Discussion resulted in the conclusion that State aid should be sought to remedy the evil and a committee was appointed for this purpose.

Surgeons for the Guard.—The following appointments in the Medical Department of the National Guard of Pennsylvania are announced: Alfred G. Wood, of Philadelphia, surgeon, assigned to Third Regiment; John C. Hirst, of Philadelphia, assistant surgeon, Third Regiment; John L. Brubaker, assistant surgeon, Sheridan Troop; Edwin A. Nicodemus, assistant surgeon, Governor's Troop.

Address on Immunity and Serumtherapy by Dr. Welch.—Dr. William H. Welch, of Johns Hopkins, addressed the students of the Jefferson Medical College March 7th, as the guest of the J. C. Wilson Medical Society. Dr. Welch, after explaining the theory of immunity, gave his personal opinion of the value of various serums and antitoxins. He stated that many failures in this line were due to the attempts to introduce methods of inducing immunity which were not based on successful experimental investigations. Various diseases were then mentioned, with comments on the status of attempts to secure immunity to each. Immunity to hydrophobia can be secured and this has proven of great value. Dr. Welch said that hydrophobia was not an extraordinarily uncommon disease and that when a case was diagnosed as such by a reputable physician it should be regarded as correct. The disease can be diagnosed with as much certainty and precision as can typhoid fever. The statistics of the Pasteur treatment were given to show its great value. This is in no sense a treatment after symptoms have begun, but is an active immunization, a sufficient time intervening between the inoculation and the disease to allow of this. The method is an effective preventive treatment. Immunization against cholera is not yet on a good experimental basis. Regarding typhoid fever a definite opinion cannot now be given as to the efficacy of attempts at immunization. The fact that some cases which are clinically typhoid fever show the paracolon bacillus instead of the bacillus typhosus complicates matters. The point was made that when the Widal reaction is negative the paracolon bacillus should be sought for. Against the plague there is a method of acquiring a quite substantial active immunity. Dr. Welch said he should submit to the Haffkine treatment were he going to an exposed place. Regarding serumtherapy two divisions were made—antitoxins and bactericidal serums. Of the former, three are on a sound experimental or practical basis, viz., diphtheria and tetanus antitoxins and antivenene. The efficacy of diphtheria antitoxin is so well established that statistics need no longer be read. The use of tetanus antitoxin is disappointing, because the symptoms appear so late that the antitoxin cannot be injected in time to be effective. It may be of some value in subacute or chronic cases. It has some prophylactic use and this should be employed more frequently in human beings who are exposed to garden soil, stable refuse, etc. Antivenene is now on a sound experimental basis. Of the bactericidal serums none are at present of great practical value, antiplague serum showing the most promise. Too many conditions must be favorable for their action—the presence of their complement, the power of destroying bacteria after uniting with the complement, etc. Antitoxins are of proven value. The bactericidal serums are yet in an experimental stage, but their further development is of very great importance.

A New Trephine.—At the Academy of Surgery, March 3d, Dr. J. Chalmers DaCosta exhibited a new instrument for trephining the skull, its use being demonstrated by the inventor, Dr. J. C. Stellwagen, a dentist and junior medical student. The instrument, although not yet perfected, is a very ingenious one, being especially adapted to cut osteoplastic flaps. It consists of a handle and shaft like an ordinary trephine, but carrying an extensible arm at right angles. This carries at its outer end a detachable knife or saw for cutting scalp or bone. The shaft has a center pin or can be rotated on a metal plate having a depressed center, it being fastened to the skull by points on one side long enough to be driven through the scalp into the bone. The instrument has given great satisfaction in the case of a child upon whom it was used.

CHICAGO.

Home for Journal of the American Medical Association.—F. W. Zander & Company have sold for John C. Nyman to Dr. E. Fletcher Ingals, a trustee representing the American Medical Association, the premises on the Northeast corner of Dearborn Avenue and Indiana Street for $42,500 cash. The present improvements consist of five two-story-and-basement brick dwellings. It is the intention of the purchaser for the present to remodel two of the houses and use the premises for the offices and publishing rooms of the *Journal of the American Medical Association.* It is said that the price paid represents a value of $425.00 a

front foot in Dearborn Avenue and $531.25 a front foot in Indiana Street.

Appointment of a Skiagrapher for Cook County Hospital.—The County Board has elected Dr. Harry J. Haiselden attending skiagrapher to the County Hospital. Dr. Haiselden will have charge of the X-ray apparatus recently installed there.

Public Health Matters.—Twenty per cent. more deaths were recorded by the Bureau of Vital Statistics of the Health Department for the week ending March 1st than for the week previous, and 46 per cent. more than for the corresponding week of 1901. The exact figures are 434 one year ago, 529 the week before last, and 634 last week. The annual rates per one thousand of population are 12.87, 15.14 and 18.15, respectively, this latter figure being unpleasantly near the average New York mortality-rate. For this city it is the highest on record for the season of the year. The causes of death showing the greatest mortality as compared with the previous week are, with the exception of pneumonia, the chronic diseases, and the result is seen in a 20 per cent. rise in the deaths of the aged, those over sixty years. Nervous diseases show 72 per cent. increase; consumption, 46 per cent.; pneumonia, nearly 35 per cent.; Bright's disease, nearly 32 per cent., and diseases of the heart, 30 per cent. There were 16 suicides and 36 other violent deaths, an increase of 53 per cent. over the number in the corresponding week one year ago and of 85 per cent. over that of the previous week.

An Analysis of Three Hundred and Twenty-Eight Operations upon the Gall-Bladder and Bile-Passages, with Observations upon the Same.—Dr. Wm. J. Mayo of Rochester, Minnesota, read a paper with this title, by invitation, before a recent joint meeting of the Chicago Medical and the Chicago Surgical Societies. A study of these cases brings out some general features of interest. Three hundred and eleven of the number were of benign origin, and the number of deaths was eight, giving a mortality of about 2½ per cent. Seventeen were for malignant disease, with three deaths, a mortality of 18 per cent. In 214 cases the stones were located in the gall-bladder or cystic duct or both, with two deaths. In about 10 per cent. of these cases there was obstruction of the cystic duct by a stone or stones were contained in the cystic duct. The after-history of many of these cases in which the cystic duct was involved and simple cholecystostomy performed was not wholly favorable, and for cases in which this duct has been obstructed or in which stones have been lodged in the duct for a length of time cholecystostomy is insufficient, and the gall-bladder should be extirpated at the primary operation if the patient be otherwise in good condition.

Stones in the Cystic Duct.—Stones in the cystic duct are often more easy to remove with the gall-bladder than without it. If the peritoneum binding it to the liver be divided on each side, the connective tissue between can be easily separated with the finger, and by using the gall-bladder as a tractor, and, if necessary, dividing the peritoneal and muscular coats just above the cystic duct, the mucous tube of the latter will strip out readily, bringing the stone with it. The mucous coat about the neck of the gall-bladder is thick and separates easily from the outer coats, while the fixation by adhesions is to the outer coats alone. At the fundus, the mucous membrane is less easy to separate, and a combination of amputation of the fundus with removal of the mucous coat from the lower portion of the gall-bladder and cystic duct, makes cholecystectomy a safe operation.

Cholecystitis.—In this group there were 34 cases, with five deaths. This mortality calls attention at once to the serious nature of the infections. All the cases in which an acute suppurative condition existed at the time of the operation, with or without stones, and all cases in which the gall-bladder was thickened and contained more or less ropy mucus and bile or sand-like sediment, without stones, were classified at the time of operation as cholecystitis. The essayist has long held the view that the dependent fundus was a mechanical factor which rendered the possibility of stone formation in cases in which the stagnation of the bile, infection of the gall-bladder and obstruction of the cystic duct were the other factors; that is to say, if the cystic duct were at the bottom, sediment would pass out first. For this reason, it seems that cholecystitis might be more liable to exist without stones in the more perfectly drained cases in which the fundus was above the level of the cystic duct. In two cases, acute suppurative cholecystitis followed typhoid fever. At the time of operation the typhoid bacillus was found in pure culture, and the patient's blood gave the Widal reaction. In both cases stones were present in the gall-bladder, but on going into the history, it could be shown almost beyond a doubt that the gall-stones existed before the advent of the typhoid, and merely determined a lowered resistance.

Stones in Common Duct.—In thirty-one cases stones were found in the common duct, with one death. In only one case was it possible to remove the stones through the cystic duct by dilating it. In 29 cases, the duct was incised and the stones removed. In five cases this was accomplished by separating the gall-bladder from the liver, and incising the free surface down to and along the cystic duct, to the common duct, and the latter was incised at the juncture. In a number of these cases the head of the pancreas was enlarged, and in six cases more or less pancreatic secretion came out with the bile.

Jaundice.—Jaundice in connection with stones in the common duct was a most variable feature. In many cases it was so slight as not to attract especial attention, and the finding of stones in the common duct was a surprise. In the majority the jaundice was marked. One patient with extreme jaundice from a stone impacted in the cystic duct at its juncture with the common duct and three with jaundice from malignant disease, died from post-operative capillary oozing. In all of these cases there were subcutaneous ecchymotic spots, looking like purpura hemorrhagica before operation. Every patient who had jaundice with this condition died in this way. No patient in whom this was not present died from this cause, although several were in extreme jeopardy.

Cholecystenterostomy.—This operation was performed three times for chronic pancreatitis and three times for malignant disease. The anastomosis was made to the duodenum twice and to the transverse colon four times. So far as he could judge, the anastomosis to the colon answered every purpose. The Murphy button was used in making the anastomosis.

Exploration.—In twelve cases negative exploration was made. This, however, includes only the cases in which the abdominal wall was incised independently for this purpose, and does not fairly represent the mistakes in diagnosis. In some of the earlier cases a small gall-bladder, with thickened walls, extensively adherent, was found, and he contented himself with loosening the adhesions. In reoperating upon one case, a ball-valve stone of small size was found in the common duct, yet so little jaundice was present as to seemingly preclude the possibility of its presence in this locality. In two cases seen since he had found a rolling stone in the common duct under precisely similar circumstances. Adhesions about a small gall-bladder should lead to a

careful exploration of the common duct before deciding that the adhesions alone are the cause of the symptoms.

CANADA.

Smallpox Coming from Quebec to Ontario.—The Ontario Provincial Health Office has received word that several men infected with smallpox have recently crossed the Ottawa River into Ontario. The men come from lumber camps and immediate steps have been taken to stop this. The Quebec Board of Health has divided that Province into ten districts with an inspector for each. The continued spread of the disease has compelled the Government to action.

Protestant General Hospital Report, Ottawa.—The fifty-first annual report of this institution has been issued. The most important event in connection with the hospital during the past hospital year has been the amalgamation with the Lady Stanley Institute. The number of patients under treatment last year was 1,400 as against 1,324 for the previous year. Of these 702 were pay patients. In the out-door departments 2,163 patients received treatment. Of these about 700 were Protestants. The fees for private patients will be raised and an effort will be made to secure a larger *per diem* allowance from the city and surrounding municipalities.

New Toronto Medical Building.—Satisfactory arrangements have at last been made with the Ontario Government with regard to the erection of the new medical building of the Medical Faculty of Toronto University. The Senate of the University will be empowered by the Government to set aside the necessary $125,000 for the construction of same. This will be on the plan of the new buildings for Harvard University. The Laboratories will be constructed on the "unit system," each one being normally 23 by 30 feet and capable of being enlarged or decreased in size for large or small classes. The new building will be located in the Queen's Park contiguous to the other buildings of the University.

Getting Matriculation by Act of Parliament.—Some Quebec students apparently think there are easier ways of securing matriculation in medicine than by the ordinary course of examinations. A bill is before or rather has been before the Quebec Legislature during the present session to permit medical students who commenced study prior to 1899 to dispense with the matriculation examination. A similar measure of relief was granted several students in 1898 who had commenced their studies prior to 1896. As the Hon. Mr. Flynn, the leader of the Opposition, put it, if this sort of thing is to continue in that Province, the qualification of a classical education for the professions had better be abolished. On the motion of the Hon. Dr. Guerin the measure received the six months' hoist by a vote of forty-five to fifteen.

New Civic Hospital for Montreal.—The question of a new civic hospital is to be discussed again by the City Council of Montreal which has long required such an institution, but never more than it did at the present time since the old hospital has been in occupation for the past year with smallpox patients. The trouble all along has been friction between the Catholic and Protestant element, the former desiring that there be two hospitals, one for the Catholics and one for the Protestants. Archbishop Bruchesi has appealed to the City Council for a separate Roman Catholic Hospital, as His Grace puts it, in the cause of peace and liberty.

Toronto Orthopedic Hospital.—The Trustees of this institution are appealing to the Canadian public for donations for their new building. It is the only hospital of its kind in all Canada which exists exclusively for the benefit of the lame, crippled and deformed. Although opened only four years ago, it has progressed far beyond the most sanguine expectations of its promoters. Twenty thousand dollars is still required to complete the alterations and additions to the new property.

Congress of French Physicians of America.—A few days ago a large gathering of French-Canadian physicians of the Province of Quebec was held at Laval University, Montreal, at which meeting it was unanimously decided to hold a congress of the French doctors of America on the occasion of the jubilee celebration of Laval University, Quebec, in June next. Dr. Brochu, Professor of the Medical Faculty of Laval, Quebec, was elected president; Dr. E. P. Lachapelle, Vice-President for Montreal and the Province of Quebec; Dr. C. Prevost, Ottawa, for the Province of Ontario, and Dr. Archambault of Cohoes, New York, for the United States. Two general secretaries were also elected, Dr. A. Simard of Quebec and Dr. le Sage of Montreal. It was also decided to ask the following to become honorary presidents to represent the universities in the Province: Dr. Craik of McGill, Dr. F. W. Campbell of Bishop's, Dr. Rottot of Laval, Montreal, and Dr. Simard of Laval, Quebec. A general committee was appointed to make all arrangements and to fix the number of days the congress would last.

Curtailing the Powers of the Quebec Board of Health.—A bill has been introduced into the Quebec Legislature by one of the members of that body seeking to amend the health laws of the Province. The member in question believes that the powers of the Board of Health are too arbitrarily exercised, especially as regards vaccination, and therefore he desires the municipal councils to have control of health affairs. Although at the present time all the civilized countries of the world are taking active measures in the suppression of smallpox, here is a legislator, in whose Province the disease has been rampant, who wishes to relax the stringency of the laws and thus permit a greater spread of the disease. The bill has been referred to the Committee on Legislation.

Toronto Clinical Society.—On the evening of March 5th the Toronto Clinical Society held its regular monthly meeting. Dr. Herbert A. Bruce reported the first case of recovery following operation for perforation in typhoid fever which has occurred in Canada. The patient, who was formerly a house surgeon in one of the Toronto hospitals, but who had commenced the practice of his profession in a small town in the western portion of the Province of Ontario, contracted typhoid fever last summer while in attendance on two or three cases in his own practice. He was attended by a fellow practitioner from a neighboring town. The case went on in the usual way until the third week, when in the middle of the night he was seized with very severe pains in the right iliac region. His medical adviser was summoned, but, as he was away in the country in attendance upon another patient, a confrère in the town was called in his place. An injection of morphine was administered which quieted the pains, and when the regular attendant arrived the following morning the patient was resting comfortably. He, however, considered that perforation of the bowel had occurred in the night and held to this diagnosis against the patient himself and three other practitioners who were summoned in consultation. Dr. Bruce of Toronto was summoned, who confirmed the diagnosis of perforation, and an immediate operation advised. This was done eighteen hours after the time of the supposed perforation. A small opening about the size of the lead in a lead pencil was found in the ileum, about eighteen inches from the ileocecal valve, and was closed in the usual way. From this the patient made a good recovery, but other trouble ensued and Dr. Bruce was

again summoned to the bedside of the patient. A subphrenic abscess had formed above the liver. This was evacuated and about two and a half quarts of pus withdrawn. After this operation the patient very nearly collapsed, but finally rallied. The patient and his medical attendant were present at the meeting when Dr. Bruce reported the case. He expressed his gratification to both gentlemen for his life which he stated he undoubtedly owed to them, especially so to his medical attendant who had made the diagnosis of perforation.

Obituary.—Dr. George W. Jackes of Eglinton, North Toronto, died suddenly on the morning of March 7th of apoplexy. He was in his fifty-first year. He had practised in Eglinton for over twenty-five years. Dr. James McLaren of the same place, also died on March 7th. He was born in 1824 and received his degree in Arts at Queen's University, Kingston, about 1850. He studied medicine in the old Toronto School of Medicine under Dr. Rolph, graduating M.B. about 1853.

GENERAL.

"Georgia Journal of Medicine and Surgery."—Dr. W. E. Fitch, founder and for many years editor and business manager of the *Georgia Journal of Medicine and Surgery*, published at Savannah, Ga., has sold his interest in the publication to his former associate and co-editor, Dr. St. J. B. Graham, who becomes editor and sole proprietor. The *Journal* under Dr. Fitch's editorial management, from the appearance of the first issue, merited the support of the profession, and gradually, year after year, made for itself a place among the best medical periodicals of this country. Dr. Fitch will devote his entire attention to the practice of his profession in Savannah, Ga.

Autopsy of Doodica.—Examination of the body of Doodica, one of the Hindoo sisters separated by operation, showed the presence of a large abscess in the lower part of the abdomen with perforation of the cecum and appendix; there was also a general tuberculous peritonitis, but no appearance of trouble at the site of operation and no trace of hemorrhage. The heart was well to the left in the normal position and there was no trace of pericarditis, pleurisy, pulmonary tuberculosis or brain disease. Death was due to tuberculous peritonitis and to the tuberculous perforation of the cecum and appendix causing blood-poisoning.

An Institute for Phototherapy.—The Queen Regent of Spain has given 10,000 pesetas for the foundation of an institute for phototherapy at Madrid.

Gregory Testimonial Banquet.—Arrangements are being rapidly completed for the Gregory Banquet to be held in St. Louis on April 17th. Hon. A. M. Dockery, Governor of Missouri, himself a physician and a former student of Dr. Gregory, will preside. Every indication points to a large attendance.

St. Louis Medical Society of Missouri.—At the last regular meeting held Saturday, March 8th, Dr. L. T. Pim read a paper on Exstrophy of the Bladder; Operation; Union by First Intention, and Dr. Sidney I. Schwab read a paper on Work as a Therapeutic Agent in Hysteria and Neurasthenia.

Second Brussels Congress for Prophylaxis of Venereal Diseases.—This Congress is to meet September 1-6, 1902, and the following subjects are suggested for discussion:

Public Prophylaxis.—Whereas, on the one hand, it is the duty of the public authorities to safeguard society against contagious diseases, which, by their frequency and by the facility with which they are spread, constitute a public danger, and while, on the other hand, quite apart from the sanitary point of view, it is their mission to protect minors abandoned by their parents. What measures of public prophylaxis, under the form of legal provisions, should be taken against venereal diseases, specially with reference to the following points? Relative to prostitution: (1.) The prostitution of minors; (2.) the actions of public bodies whether in the interest of public morality and tranquillity, or from a sanitary point of view; (3.) procurers and bullies. Not associated with prostitution: (1.) The protection of minors of both sexes; (2.) the organization of measures of relief for those suffering from venereal diseases; the duties of charitable institutions to those so suffering; (3.) suckling by wet nuses; contagion by midwives and nurses; arm-to-arm vaccination; contagion in factories and workshops by means of instruments of labor; registry offices, etc. Is it necessary to apply the principles of civil and penal responsibility for the transmission of venereal diseases?

Individual Prophylaxis.—Taking into consideration that if the public authorities have to take prophylactic measures against venereal diseases, the duty of self-preservation is incumbent on every one; on the healthy, by the avoidance of all dangerous contact with an infected subject, and on the diseased by avoiding the possibility of infecting others. (1) What are the best means of enlightening the youth and the general public on the social and individual dangers of syphilis and gonorrhea, as well as the methods of contagion of these two diseases, direct or indirect? (2.) How can one best facilitate individual prophylaxis by means of charitable institutions (dispensaries, refuges, etc.) and the medical treatment of patients of both sexes suffering from syphilis or gonorrhea?

Statistics.—What should be the uniform basis on which the statistics of venereal diseases in all countries should be formulated?

American Association of Urologists.—This Association was organized on February 22, 1902, essentially for the purpose of the further development of the study of the urinary organs and their diseases. Although most of the founders of the Association are specialists in genito-urinary diseases, membership is not limited to those engaged exclusively in this specialty. Thus, gynecologists who embrace renal and vesical surgery in their work are among the founders, as there are several who devote themselves to the microscopy and chemistry of the urine, as well as a number of practitioners interested in the study of the kidney from a medical standpoint. The Association consists of active, corresponding and honorary members, and is in great measure modeled upon the plan of the Société Française d'Urologie, modified to suit American circumstances and conditions. Thus, whenever possible, the branch associations, throughout the United States, British Possessions and Spanish America will hold their meetings on the same evenings as does the parent association in New York (the first Wednesday in each month). The work of the Association is principally clinical, for the demonstration of new methods of the technic of examination and treatment. The annual meeting of the American Association of Urologists will be held on the last day and the day following the annual meeting of the American Medical Association. The officers of the Association are: Ramón Guiteras, M.D., President; Wm. K. Otis, M.D., Vice-President; John Van der Poel, M.D., Treasurer; Ferd. C. Valentine, M.D., Secretary; A. D. Mabie, M.D., Asistant Secretary.

Association of American Physicians.—The Preliminary program of the Seventeenth Annual Meeting of the Association of American Physicians, to be held in Washington, D. C., on April 29th and 30th and May 1, 1902, includes the following papers: President's Address, by James C. Wilson, Philadelphia; Pneumococ-

cus Arthritis, by James B. Herrick of Chicago; A Case of Osteitis Deformans, by R. H. Fitz of Boston; A Case of Osteitis Deformans and one of Hyperostosis Cranii, by Morton Prince of Boston; Report of Cases of Bronchiectasis Following Influenza-Pneumonia, by W. W. Johnston, Washington; Pulsations in the Chest, by Arthur R. Edwards of Chicago; Spontaneous Non-tuberculous Pneumothorax, by M. Howard Fussell of Philadelphia: The Prognosis of Pleurisy with Effusion, by Richard C. Cabot of Boston; Healed Ulcerative Endocarditis, by James B. Herrick of Chicago; Tuberculous Pericarditis with Remarks upon Paracentesis and Incision, by Beverley Robinson of New York; the Condition of the Heart in Pregnancy, by Alfred Stengel and W. B. Stanton of Philadelphia; A Report of Cases of Thermic Fever Treated at the Pennsylvania Hospital in the Summer of 1901, by M. J. Lewis and F. A. Packard of Philadelphia; Results of Trauma of the Pancreas, Charles G. Stockton of Buffalo; Clinical Manifestations of the Early Stage of Cirrhosis of the Liver, by Frank Billings of Chicago; Drainage in Chronic Intestinal Catarrh: Its Importance and Technic, by Norman Bridge of Los Angeles; Intestinal Hemorrhage: Its Relation to Duodenal Ulcer, by Henry Jackson of Boston; A Clinical and Experimental Investigation of the Value of Gelatin as a Hemostatic, Alfred Stengel and D. L. Edsall of Philadelphia; Prognosis and Treatment of Tuberculous Peritonitis Based on the Massachusetts General Hospital Experience for the Past Ten Years, by Frederick C. Shattuck of Boston; Angiomyositis, by W. S. Thayer of Baltimore; Splenic Anemia and Its Varieties, by William Osler of Baltimore; Report of a Case of Lymphatic Leucemia, by D. D. Stewart of Philadelphia; Mitosis in Circulating Blood, by George Dock of Ann Arbor; The Pathology of Pernicious Anemia with special reference to the Changes in the Hemolymph Glands, by Eldred Scott Warthin of Ann Arbor; Pathology of Adrenalin Diabetes, by C. A. Herter of New York; A Case of Cystic Degeneration of the Kidneys, by I. N. Danforth of Chicago; A Study of Bacterial Cells, by Victor C. Vaughan of Ann Arbor; The Surface Action of Metals on Bacteria, Toxins and Enzymes, by F. E. Novy of Ann Arbor; Report of the Presence of Anguillula Aceti in the Urine of Two Patients Mistaken for Strongyloides Intestinalis, with Lantern Slide Demonstration, by Frank Billings and Joseph L. Miller, Chicago; A Case of Hematoporphyrinuria, by James Tyson and Alfred C. Crofton of Philadelphia; Histological Alterations of Cytotoxinic Intoxication, by Simon Flexner of Philadelphia; An Estimate of the Amount of Toxin in the Blood of a Horse Infected with Tetanus, by B. Meade Bolton and Carl Fisch of St. Louis; and Comparative Toxicity of Ammonium Compounds, by B. K. Rachford and W. H. Crane of Cincinnati.

Medical Clerk and Translator.—The United States Civil Service Commission announces that on April 22, 1902, an examination will be held for the position of medical clerk and translator in the Bureau of Animal Industry, Department of Agriculture.

The examination will consist of the subjects mentioned below, which will be weighted as follows: (1.) Translation of medical German, 25. (2.) Translation of medical French, 25. (3.) Translation of medical Italian, 10, (4.) Translation of medical Spanish, 10, (5.) Technical bibliographic work in medicine and zoology, 10. (6.) Medical and zoological terminology and nomenclature, 10. (7.) Experience, 10. Age limit, twenty years or over. From the eligibles resulting from this examination it is expected that certification will be made to the position of medical clerk and translator in the Bureau of Animal Industry, Department of Agriculture, at a salary of $720 per annum, and to other similar vacancies as they may occur. This examination is open to all citizens of the United States who comply with the requirements. Competitors will be rated without regard to any consideration other than the qualifications shown in their examination papers, and eligibles will be certified strictly in accordance with the civil service law and rules. Persons who desire to compete should at once apply to either the United States Civil Service Commission, Washington, D. C., or to the secretary of the local board of examiners at the places mentioned in the accompanying list, for application Forms 304 and 375, which should be properly executed and filed with the Commission at Washington. The regulation requiring that applications be filed at least ten days prior to the date of the examination will be waived in accepting applications for this examination.

St. Joseph's Sanitarium.—Plans for an extensive addition to St. Joseph's Sanatorium, at Silver City, New Mexico, are completed, and the work will be begun shortly. This institution, which was initiated only last fall, has outgrown its present quarters and the new building is a necessity. The completed plant will form four sides of a square or court; that is, old California Mission style. The building will be but one room thick and one story high, with porches outside and inside, upon which the rooms will open by means of French windows. The kitchen, dining-room and research laboratory will be in separate buildings. A complete hydrotherapeutic apparatus will be installed. The management of the institution is entirely under the control of the Advisory Board. The immediate care of patients is entrusted to Dr. W. T. Williams and Dr. E. S. Bullock is the pathologist and diagnostician. The plan of treatment pursued is the careful application of the Brehmer principles in an ideal climatic environment.

Obituary.—Dr. Charles O. Carpenter, aged sixty-three, and one of the best-known physicians and surgeons of Massachusetts, died last week of pneumonia at his home in Holyoke.

Prof. Moriz Kaposi of the University of Vienna, the celebrated dermatologist, died March 6th. He was born at Kaposvar, in Hungary, on October 23, 1837. In 1879 he succeeded Prof. Hebra at the University of Vienna. His principal work, on the pathology and therapy of skin diseases, has been translated into several languages.

Dr. W. Fontaine Lippitt, a distinguished citizen and physician of Charlestown, Jefferson County, W. Va., died March 11th in his seventy-first year, at his home in that city. Dr. Lippitt was a son of the late Rev. Dr. Lippitt, who was for many years an eminent clergyman in the Protestant Episcopal Church, occupying a position as professor in the Virginia Theological Seminary, near Alexandria, and was closely related by marriage with the descendants of George Washington. Dr. Lippitt's widow and eight children survive him.

OBITUARY.

CHRISTIAN FENGER, M.D.

This famous surgeon died in Chicago Friday evening, March 7th, of pneumonia, after a week's illness. He was attended by Drs. Henry B. Favill, Frank Billings, and J. B. Herrick. Dr. Fenger's name and fame are known wherever modern surgery is practised. He had gained an international reputation in his profession and was classed as one of the foremost surgeons of his time. His advent in Chicago, a quarter of a century

ago, meant much to the progress of modern medicine and surgery in the West. He was a profound teacher of medicine and surgery based on sound pathology. During the last thirty years he contributed more than eighty articles to medical literature, and all of his writings breathe the same spirit of critical inquiry and originality of thought. They have all found a permanent place in medical literature. He was a member of the leading medical societies in this country as well as in Europe, and had served as surgeon on the hospital staffs of Cook County, Presbyterian, Tabitha Norwegian, Passavant Memorial, Lutheran, German and German-American Hospitals.

Dr. Fenger was born in Copenhagen, Denmark, November 3, 1840. While still a medical student, in 1864, he served as surgeon in the war between Denmark and Germany. He was graduated from the University of Copenhagen in 1867, and for two years was assistant in Wilhelm Mayer's Ear Clinic in Copenhagen. At the outbreak of the Franco-German war he became surgeon in the Red Cross Ambulance Corps, serving in this capacity throughout the war. From 1871 to 1874 he

CHRISTIAN FENGER, M.D.

was prosector and during 1873 and 1874 privat-docent at the Copenhagen City Hospital. A year later he was a member of the Sanitary Council and surgeon to the Khalifah of the district of Cairo.

Zeal for thorough scientific education led Dr. Fenger to encourage thoroughness in others as well as to make it the rule of his own life. To him is due the decision of many of the younger surgeons of the West to pursue post-graduate courses in the European universities.

Starting at the Cook County Hospital, he soon was given honor by other institutions. In 1880 he was curator of the Rush Medical College Museum; in 1884 professor of clinical surgery at the College of Physicians and Surgeons; nine years later professor of clinical surgery at Chicago Medical College. Rush Medical College honored him in 1899 with the chair of clinical surgery. Other hospitals than the Cook County claimed a share in his work. He is said to have performed between seven thousand and eight thousand postmortem examinations.

On the occasion of Dr. Fenger's sixtieth birthday, a testimonial banquet was given to him at the Auditorium Hotel by the medical profession. Nearly six hundred guests were present from Chicago and the Middle West and Northwest; also some prominent surgeons from the East. A loving cup was presented to him. Not long before the banquet Dr. Fenger had been honored by the King of Denmark, who conferred upon him the Order of Ridder of Dannebrog.

One of the regrettable features of Dr. Fenger's death is that it came before he had carried out a cherished idea of enjoying a country house. He had sold his city residence and this spring was to build in Winnetka, where he had spent his summers for several years, a Norwegian house, following to the minutest detail the architecture and arrangement of houses in his fatherland. He left a widow and two children. Up to his death he held the presidency of both the Chicago Medical and the Chicago Surgical Societies.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, March 1, 1902.

THE LEGAL RECOGNITION OF MIDWIVES—THE PIONEER OF THE OPEN-AIR TREATMENT.

Legislation for the regulation of obstetrical practice by midwives has been strongly opposed by a section of the medical profession in this country ostensibly in the interest of poor women suffering from the curse pronounced on Eve, but really from a less altruistic motive. It has been pointed out over and over again that legislation on the subject was urgently needed; that the medical profession would not be affected in any way—except perhaps beneficially—by such legislation inasmuch as the women for whom skilled help in their hour of trouble is to be provided are too poor to pay a doctor; and that Parliament would sooner or later be driven by the voice of the people to legislate on the subject. The Government has been in no hurry and has hitherto left the question an open one as to which its supporters could take any course they pleased. It has also sought to ascertain the views of the medical profession on the subject. Unfortunately, the profession, under the evil inspiration of a band of short-sighted irreconcilables, has taken up an attitude of mere selfish obstructiveness, and the Government, which would doubtless have been glad to give due weight to the advice of the General Medical Council if the profession had not allowed its feeling to be misinterpreted by a small band of noisy fanatics, is now evidently determined to dispense with any assistance from that quarter. On February 26th a bill for the legalization of the midwife passed its second reading in the House of Commons. Last year a measure which would have given the medical authorities a fairly tight hold on the midwives was defeated owing to the opposition of Sir Walter Foster and one or two other medical Members of Parliament. The present bill practically leaves the midwife uncontrolled. Sir Walter Foster, with the help of Sir John Batty Tuke, also a physician, again tried to wreck the bill, but Dr. Farquharson and Sir Michael Foster, the professor of physiology at Cambridge, strongly supported the bill, and the majority of the House had clearly made up their minds to pass it. An old Parliamentary hand, to use a phrase consecrated by Gladstonian usage, has told me that he has never seen such unanimity displayed on any subject before. The Government, which has a large and well-disciplined majority at its back, can easily pass the measure; and from what I hear it is determined to do so. The bill has virtually the support of every

section of the House, and Sir Walter Foster, who is a politician first and a physician afterward, will doubtless see the prudence of executing a strategical movement to the rear. Of course, in Parliament the unexpected often happens and the bill may even yet fall into one of the numerous traps which the rules of parliamentary procedure set for unwary legislators. But the chances are that it will become law in the course of the present session. If the profession does not like it, the Government might reply, *"Tu l'as voulu, Georges Dandin!"* The bulk of the profession, however, recognizes the need of legislation, but the controversy on the subject has been so acrimonious that men of moderate counsels did not care to take part in it. Hence, the voice of a handful of demagogues and men whose aim appears to be to transform the profession into a trades-union has been allowed to go forth as that of the medical profession.

The New Sydenham Society has just issued a volume containing among other things a reprint of "An Essay on the Treatment and Cure of Pulmonary Consumption on Principles Natural, Rational and Successful; with Suggestions for an Improved Plan of Treatment of the Disease Among the Lower Classes of Society; and a Relation of Several Cases Restored from the Last Stage of Consumption to a Good State of Health," by George Bodington. The work was originally published in 1840 and was totally forgotten till a few years ago when the open-air treatment of phthisis began to come into fashion. Bodington, defying that bogey of physicians of the early part of the nineteenth century, "phlogiston"—which he called the "raw head and bloody bones" of medical science—fed his consumptive patients generously, and initiated what was practically a system of sanatorium treatment in which great attention was paid to the dryness, mildness and purity of the air in which the patients lived, to "systematic arrangements with regard to exercise, diet and treatment, with the watchfulness daily—nay, almost hourly—over the patient by a medical superintendent." Bodington spoke out, with no uncertain sound, in condemnation of the practice prevalent in his day of shutting consumptive patients up in a close room, from which the atmospheric air was as far as possible excluded, "thus forcing them to breathe over and over again the same foul air contaminated with the diseased effluvia of their own persons." In speaking of treatment by the inhalation of gases of various kinds, he says that "the only gas fit for the lungs is the pure atmosphere freely administered without fear," adding that "its privation is the most constant and frequent cause of the progress of the disease." He goes on: "To live in and breathe freely the open air, without being deterred by the wind or weather, is one important and essential remedy in arresting its progress —one about which there appears to have generally prevailed a groundless alarm lest the consumptive patient should take cold."

One of the cases related in illustration of the beneficial effects of the open air treatment is that of a young girl of sixteen who in 1835 was believed to be doomed to an early grave. She was treated by Bodington on the principles just set forth, and in 1839 was in perfect health. Only a week ago (February 22d) the *British Medical Journal* published a letter from the patient herself stating that, now in her eighty-first year, she is still in fairly good health and able thankfully to enjoy the many mercies which surround her in her daily life. Throughout the sixty-six years which have elapsed since she was practically under sentence of death she has on the whole had remarkably good health.

Bodington spent the greater part of his professional life in charge of a lunatic asylum at Sutton Coldfield in Warwickshire. In the matter of the treatment of consumption he was far before his time; his book was practically killed by the reviewers and thus one of the most important advances in the treatment of disease made since the days of Hippocrates was delayed for half a century. Truly in medicine the light often shineth in darkness and the darkness understandeth it not!

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

SERPIGINOUS ULCER OF THE CORNEA—VACCINATION GRANULOMA—FUNCTIONAL MUSCULAR INSUFFICIENCY OF THE HEART VALVES—PARALYSIS OF THE QUADRICEPS FEMORIS —ASBESTOS UTENSILS FOR THE SICK—COLIC, BLEEDING AND INFLAMMATION OF THE KIDNEYS.

The German societies have recently listened to important contributions on a large variety of topics of which the following are the best:

Velhagen, at the Medical Society in Chemnitz, December 11, 1901, read a paper on the early diagnosis of serpiginous ulcer of the cornea and stated that he has for some time examined for pneumococci by means of cover-glass preparations, all the cases which came to him suffering with infiltration and ulcer of the cornea. In all cases of destructive serpiginous ulcer he found these germs usually in pure culture. On one occasion an infiltration was caused by a splinter of wood. Pneumococci were present and he cauterized the lesion with successful results. On three other occasions no pneumococci were found, although there was a rather large ulcer, iritis, hypopyon, and, in one patient, even dacryocystoblennorrhea. These patients recovered with better vision than those treated by the cautery.

Naether read a paper on the subject of granuloma following vaccination. This had occurred in about seven per cent. of his five hundred cases of revaccination, usually about the twentieth day after the vaccination and at the site of the scar where neither nodules nor pustules nor signs of inflammation were present. On the other hand there were granulation tumors of the size of ordinary beans which were diagnosed with the microscope as well as clinically. The cause of these seems to be one class of bacilli belonging to the pseudo-diphtheritic group which Nauwerk has cultivated both from lymph and from granulation together with staphylococci. This latter authority states that in ordinary pus these germs are not as harmless as many authors indicate.

F. Krause, at the Berlin Medical Society, January 15, 1902, reported a case operated on four years ago for paralysis of the quadriceps femoris. A cure was obtained by a transplantation of the flexor muscles of the thigh. When two years old the patient had a spinal paralysis which left the quadriceps femoris very much impaired and withered with a later contracture at the knee. Now, however, after the operation the patient possesses a certain gait, although, on account of the shortening of the limb, with limping. Electrical reaction showed the quadriceps muscle entirely paralyzed, while by stimulation of the flexor muscles the leg was promptly extended upon the thigh. At the operation the flexor muscles were liberated on the outer and inner aspects of the thigh and their tendons were sewed on either side of the patella.

Kornfeld, at the Society for Internal Medicine at Berlin, on January 13, 1902, showed numerous utensils for the sick. These consisted of about 95 per cent. of asbestos, which the author states would on the long run be much less costly than the renewal of furniture and utensils made of wood. Both characteristics, cheapness and indestructibility by fire, induce one to try them.

They can also be sterilized easily by making them red hot. The articles which he suggests are spit cups, mouth spatulæ and similar instruments. He hoped to succeed in the future in making chairs, closets and the like of the material.

Senator read a paper on colic, bleeding and inflammation of the kidneys, in which he made the following points. James Israel has recently published accounts of the results of his operation of splitting the kidney for colic, bleeding and even inflammation of the organ. Certain specialists in genito-urinary diseases have also been following his example. Senator made his paper a contention against these observations. Israel has had such good results after these interventions that in certain cases he assumes there is a strong hyperemia of the kidney which goes on to the stretching of the capsule of the organ and then to great pain. All of these conditions, he claims, are relieved by the operation of splitting the kidney. In a similar manner, by relieving the tension, bleeding may be overcome and occasionally a good influence exerted upon inflammation itself. Senator cured a case of renal hemophilia as early as 1890 by removal of the diseased organ, but he now believes that the cases which Israel cites did not, for the most part, present this condition of stretching of the capsule. He makes these observations after having seen a number of such cases himself and after noting that in Israel's own report of fourteen cases the kidney was noted as being soft and flabby or in a similar condition. Senator therefore thinks that this explanation of renal colic is not satisfactory and that this form of surgical operation is hardly justifiable. Furthermore, if the object of this operation be to cure congestion or bleeding, the bleeding itself would be the best method of relieving the congestion. Naunyn, indeed, reported three cases of rapid bleeding in inflammation of the kidney which recovered without any operation whatever. Pel and Rosenstein have lately declared themselves against the operation, while surgeons and genito-urinary specialists have taken it up with eagerness. Finally, as to nephritis, only small sections were removed and examined microscopically. It is probably true that in no case was there well-developed Bright's disease, but rather localized affections of the kidney. Israel himself, however, did not go to such extremes as his imitators who have proceeded without any consideration.

Lenhartz, at the Physicians' Society in Hamburg, January 7, 1902, delivered an oration celebrating the twenty-fifth anniversary of E. Fraenkel which occurred on January 1, 1902. That date marked twenty-five years of unbroken service as prosector in the various institutions in Hamburg. The speaker paid a tribute to his accomplishments, intelligence, wisdom, scientifically critical attitude and powers as a teacher. He closed by stating that the greatest number of physicians practising in Hamburg valued their relations with Fraenkel and considered themselves fortunate therein. His chief service to them has been that of furnishing the means of knowing much in pathology.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

Stated Meeting, Held February 18, 1902.

E. Franklin Smith, M.D., Chairman.

Etiology of Endo- and Pericarditis.—Dr. Frederick A. Packard of Philadelphia read a paper involving the consideration of some points in the etiology and diagnosis of endocarditis and pericarditis. He dwelt particularly on the fact that microbes play an important rôle in the etiology of endocarditis and that even when they have disappeared completely from the valve lesions at autopsy, this is no sign that at some time they were not present to begin the series of pathological changes. There is, however, a chronic endocarditis that develops without inflammation and that is due to high tension in the arterial system. This can no more be considered truly inflammatory than can the changes in a cyanotic liver be considered to be due to a true hepatitis.

Pericarditis is a more purely local disorder than is endocarditis, because of the fact that it has no direct connection with the blood-stream. One of the functions of the pericardium, recently insisted on, is its power to prevent overdistention of the heart. In this it acts like the cover of a football or the second bulb in a Paquelin cautery. Dr. Packard dwelt particularly on certain symptoms that should arouse suspicion of the pericarditis. One of these is delirium, without the hyperpyrexia of rheumatism or renal involvement; when a delirious patient is admitted to the hospital it is always well to examine the precardium. Another suspicious sign that has recently been pointed out is an inequality of the pupils. Dr. Packard brought out the fact that the usual diagnostic symptom of triangular dulness with the base downward is not often present in pericarditis. The most pathognomonic symptom seems to be dulness in the fifth interspace to the right of the sternum. Dr. Packard's paper will appear in full in a subsequent issue of the Medical News.

Dr. William H. Porter said that there were many non-inflammatory conditions of the pericardium that must be borne in mind. The milk-white patches often found postmortem are significant of fibrotic changes of a not very serious character. Punctate hemorrhages into the pericardium are not unusual and occur in such diseases as scurvy and leucocythemia and in certain of the infectious fevers. New growths are rare and yet occur with sufficient frequency to make them of interest even to the general practitioner. Gummatous formations are more frequent than others. Tuberculous lesions of the pericardium are really inflammatory, but because of their slow course they resemble the non-inflammatory conditions. Miliary tuberculosis is the most frequent form and may be accompanied by hemorrhagic exudation. The true inflammatory processes in the pericardium are mainly serous and fibrous; there is also the severer form of purulent pericarditis. The endocardium is less vascular than the pericardium and has therefore less tendency to redness or to hemorrhagic conditions than the pericardium. It is manifest that in inflammatory conditions causing exudation of serum this material is carried away by the blood-stream. Congestive conditions of the layer beneath the superficial covering of the endocardium is the first change in inflammatory conditions, and this causes an overgrowth of the superficial layer of cells. There are various grades of proliferation and after the proliferative process degenerative changes may set in, causing a deposit of fat or setting up ulceration or calcification. When small pus foci occur the process is known as malignant endocarditis.

Simple endocarditis is not, as a rule, bacterial in origin, but rather toxic. The toxins are manufactured by micro-organisms situated somewhere in the body, but usually not localized on the tissues of the valves themselves. As a rule, micro-organisms are not found in the vegetation on the heart valve at autopsy. It is not improbable that the changes thus seen are rather the result of a previous inflammatory condition than of an actually progressive inflammatory process.

Treatment of Endocarditis.—The first consideration with regard to endocarditis must necessarily be

the possibility of its prevention. Unfortunately, however, not much practical good can be done in this way. It is impossible to stop the rheumatic process to which the endocarditis is usually due, and the other great causes of endocarditis, Bright's disease and syphilis, are equally obstinate to curative treatment. One can, by supporting the system, enable it to throw off the symptoms. The most important idea for this is absolute rest for a prolonged period.

Treatment of Pericarditis.—For the discomfort that is so often characteristic of pericarditis an ice-bag or a flyblister to the precordium may prove useful. The blister acts reflexly and probably also relieves pressure upon sensitive nerve-endings in the pericardium. With regard to tapping the pericardium there is no established rule; if the heart's action become embarrassed, it must be relieved by aspiration. Unlike tapping for pleurisy this operation in pericarditis is never without its dangers. If, however, a pericardial effusion resist all absorptive treatment, tapping of the pericardial sac, in order to relieve the heart of the inconvenience and interference with its action due to the presence of the fluid, is not only justified but indicated. An article by Dr. Porter on this subject will appear in a subsequent issue of the MEDICAL NEWS.

Dr. Stephen Burt, in discussing the papers on endocarditis and pericarditis, said that valvular lesions do not represent an active process, but are the remains of an inflammatory condition. Usually they are not progressive, hence it may well happen that people with a limited valvular lesion may live on for many years. Dr. Burt has recently seen a patient who has lived for more than forty years with a distinct aortic lesion. The prognosis of these cases is not nearly so fatal as has been thought and the life insurance companies are gradually coming to the realization that many of these cases may well be insured under certain conditions. With regard to the diagnosis of pericarditis, Dr. Burt considers that the superficial character of the murmur in pericarditis is the most distinctive sign. Pericarditis is undoubtedly often missed. With regard to the treatment of endocarditis Dr. Burt considers that digitalis, in spite of supposed physiological objections that have been urged for certain conditions, must always be the sheet anchor.

Diagnosis of Endocarditis.—Dr. Conner considers that it is unfortunate that students somehow get the idea that a valvular lesion can be diagnosed by means of the murmur alone. The murmur is only one, and not always the most important, physical sign of the existence of a heart lesion. The character and position of the apex beat and the size of the heart are at least as important as the murmur. With regard to the diagnosis of pericarditis, Dr. Connor says that no single pathognomonic sign can be depended on. Not infrequently dilatation of the heart is associated with pericarditis and dulness may be found at the right border of the sternum and at the fifth interspace without necessarily indicating an affection of the pericardium. Some of the signs that arouse suspicion of the presence of pericarditis are important. Dr. Connor has now under observation a case in which inequality of the pupils exists.

Malignant Endocarditis Without Germs.—Dr. Lambert said that it seems not impossible for a typical case of malignant endocarditis to terminate fatally within a few days without any micro-organisms in the lesions being disclosed at autopsy. He has recently seen a case of rheumatism complicated by endocarditis, with the typical temperature curve of malignant endocarditis, which proved fatal. Five cultures taken from the valve, some of them with anaerobic precautions, failed to develop and the result as regards the presence of microbes was absolutely negative. He has also seen a case of septic temperature followed by sudden death in which infarcts in the pericardium and vegetation on the valves were found, and yet it was impossible to obtain cultures from the lesions.

Dr. Lambert considers that a very important diagnostic auxiliary in cases of suspected pericarditis is percussion with the patient bending well forward. The pericardial sac is so constructed that small amounts of fluid gravitate back from the chest-wall and so cannot be detected by percussion. If the patient bends forward, however, the fluid can be recognized rather easily and the area of dulness on both sides of the heart will be found to be increased. This is a bit of diagnostic technic that Dr. Chvostek of Vienna insisted on and frequently used with excellent results.

Valvular Degeneration.—Dr. Quimby said that there are two facts that must be borne in mind with regard to the development of valvular endocarditis. The mitral valve curtain is not a valve in the ordinary sense of the word like the aortic valve, but is a partition drawn up against the column of blood and holding it up. This physiological fact explains the mechanism of the Flint murmur which is so often a matter of dispute. It must be remembered that valvular defects developing after middle life are not always inflammatory, but may be degenerative. They are the result of pure traumatism, of irritative properties of the blood and disturbance of the muscular power of the heart. Men who work at high tension develop a progressive murmur, the result of the overuse of the tissues. The prophylaxis of these lesions is the relief of high arterial tension by a let-up in the method of life that provides for more relaxation.

Hydrophobia and Pericarditis.—Dr. James J. Walsh said that the diagnosis of pericarditis is not difficult if it is suspected. The condition is often overlooked because attention is not called to the precordial region and careful search for the physical signs of pericarditis is not made. Extraneous signs, then, that arouse suspicion of the existence of pericarditis are important. Dr. Packer has called attention to the delirium that often accompanies pericarditis and to the inequality of the pupils that may occur. French writers have called attention to the fact that the involvement of the recurrent laryngeal nerve, because of pressure within the pericardium, may lead to the development of a set of symptoms resembling hydrophobia. There is a deglutition spasm brought on by even the thought of food which resembles that seen in true rabies and which is due to the same nervous reflex. Many of the cases of hydrophobia said to occur years after a dog-bite are really due to the existence of an overlooked pericarditis. Dr. Walsh remarked that another bit of technic in use at the Vienna hospital, the examination of patients in the knee-elbow position, is often useful in ascertaining the presence of small quantities of fluid in the pericardium which have escaped other methods of detection.

Mortality From Pneumonia.—Dr. Stephen D. Burt said that the average length of life in this country has increased very notably. In 1890 it was about 31.4 years. According to the census of 1900 it is now over 35 years. There has been a decline of ten per cent. in the mortality of the large cities. Notwithstanding this there is an increase in the mortality from pneumonia. The three most prominent causes of death in the mortality statistics are pneumonia, consumption and heart disease. Consumption during the last decade has increased very considerably in fatality. Heart disease is still as important as ever in the statistics, but it is probable that better diagnostic methods have revealed more cases than before and that there is really

a lessened mortality. Pneumonia, however, is undoubtedly taking off many more people than formerly; in the winter and early spring its mortality is almost in direct ratio to the density of the population. It attacks especially the weaklings and the old and seems to be particularly fatal in the negro race.

Infection of Pneumonia.—Pneumonia is infectious through the sputum of patients suffering from the disease. Owing to the fact that pneumonia patients are confined to their rooms, this is not so widely scattered as in the case of tuberculosis, but there is undoubtedly more danger of contagion than has been thought. It is well known that epidemics of the disease occur in barracks, hospitals, asylums and schools. This feature of the disease was recognized even before the discovery of the microbic cause of pneumonia. The disease would undoubtedly spread much more widely than it does, except that a special predisposition seems to be necessary for its acquirement. Overcrowded cars and ferries and overheated dwelling-places without proper ventilation not only furnish the favorite conditions for the pneumococcus, but also foster conditions of the mucous membrane that lower resistive vitality. The pneumococcus exists in the mouth of even healthy individuals and it is probable that the changes which lower resistive vitality make it virulent.

Prophylaxis of Pneumonia.—The best prophylaxis of the disease consists in avoiding exposure to inclement weather, especially at times when the system is not over strong, and in avoiding crowded places of all kinds. Ill-ventilated meeting-places, be they churches, theaters, public halls, or schools, are the breeding-places of pneumonia. Discrimination must also be exercised with regard to food, to water and especially to air; the mouth should occasionally be washed out with some mild antiseptic solution, which, however, should possess sufficient strength to be effective. Rinsing the mouth with formaldehyde, twenty drops to the pint of water, is undoubtedly an excellent precaution. The sputum of patients suffering from pneumonia should be disinfected.

City Sanitation.—Little as it is realized, there is the strongest kind of solidarity as regards health between the rich and poor in large cities. The existence of the sanitary tenement-house saves the mansion from many an otherwise annoying or perhaps fatal illness. There were 10,500 deaths from pneumonia in New York during the year 1901, and yet few cities are so healthfully situated. Its island location, with abundance of sunshine during the year and proximity to the ocean, makes it eminently salubrious if but proper care be taken of sanitary conditions. More careful ventilation of theaters, shops, churches, schools is needed. The streets should be washed and swept as they are in Paris and arrangements should be made by which offending material, such as the excrement of animals and human sputum, should not be allowed to be cast into the streets. No doubt, improvement has come along these lines of late, but there is still much to be done. The reward of hygienic regulation is easy to foresee.

Prevalence of Pneumonia.—Dr. W. Gilman Thompson said that pneumonia is undoubtedly more prevalent than it used to be and its frequency in the statistics is not due merely to better diagnosis. Watson, in his Text-Book of Medicine issued thirty years ago, said that he saw perhaps five to six cases of idiopathic pneumonia in a year; for a man in extensive hospital practice this was, of course, an extremely small number. There is no doubt that epidemics of pneumonia may occur. Dr. Thompson has seen such an epidemic in a ward of the Presbyterian Hospital, among patients who had been for a considerable time in the institution, as the result of the admission of a pneumonia patient. It is always insisted that lowered vitality is necessary for the contraction of pneumonia, but it will be found to occur almost as frequently among people of robust health.

Treatment of Pneumonia.—Dr. Beverley Robinson said that pneumonia is undoubtedly contagious and seems to have a tendency to affect especially relatives of the patient who are run-down by the worry and loss of sleep consequent upon nursing. Care should be taken, therefore, to disinfect the patient's sputum and the hands that come in contact with this secretion. Undoubtedly the treatment of pneumonia by an antiseptic, one of the creosote preparations, for instance, helps to prevent the spread of the disease. Probably no remedy will abort the disease, but the creosote preparations add considerably to the comfort of the patient. Dr. Robinson thinks that Dr. L. Nammack's excellent résumé of the four things necessary in the treatment of pneumonia cases should be in every practitioner's mind, namely, strychnine, nitroglycerin, oxygen and alcohol. Dr. Robinson suggests, as Opie said to the man who asked him what he mixed his paints with, that these four remedies be mixed with brains.

Relative Increase of Pneumonia.—Dr. Andrew H. Smith said that while pneumonia is actually on the increase, this is really relative to certain factors. Pneumonia is especially fatal in old persons and at the present time, as the result of better hygienic surroundings, persons live to an older age than before. Besides, in the longer average duration of life, individuals have more opportunity to pick up the pathological conditions of heart and kidneys, for instance, that make the prognosis of pneumonia so much more serious than formerly.

Varied Virulence.—The pneumococcus is very varied in its virulence; in the laboratory it is very well known that while some specimens are very fatal to animals, others produce scarcely any fatal effect. Epidemics of pneumonia are prone to occur, especially when the disease develops in very virulent form. It is probable that the ordinary mucous membranes of the body are not favorable to the development of the pneumococcus. It does not seem to grow well on ciliated epithelia, while serous membranes and especially mucous membranes without cilia, are favorable locations for its multiplication. Anyone who has tried to obtain specimens of the microbe knows how fastidious it is with regard to growing on artificial culture-media. It is extremely difficult to grow for successive generations in the laboratory. When the pneumococcus reaches the air-cells in the lungs, however, it grows very rapidly and pneumonia results. When the inflammatory process reaches the boundaries of a lobe it is mechanically arrested, hence the occurrence of lobar pneumonia.

Treatment of Pneumonia.—The pneumococcus is not very resistant to antiseptic influences and so there is the temptation to use antiseptics in the treatment of pneumonia. Some of the creosote preparations, especially creosote carbonate, under the form creosotal, have proven especially useful; it is easier to take than any of the other forms of creosote. When this drug is used ninety per cent. of the cases of pneumonia go on to resolution by lysis instead of by crisis. Other remedies must not be neglected and nitroglycerin is especially valuable, being, in this disease of greater worth than digitalis. When the patient becomes blue it is a signal for the free use of nitroglycerin, rather than digitalis.

Constitutional and Local Infection.—Dr. Frederick A. Packard said that it is perhaps a mistake in present-day medicine to regard such diseases as typhoid

fever and pneumonia as constitutional with local manifestations. Typhoid fever is a primary infection of the intestine and only secondarily infects the general system. Pneumonia consists of an infection of the lungs and the resulting toxemia is only secondary. From this standpoint the therapeutics of these diseases is more encouraging and a truer idea of the condition is obtained.

Pneumonia at Groton.—Dr. Alexander Lambert said that the series of cases of pneumonia that occurred at Groton was not, in his opinion, an epidemic of pneumonia, but the coincidence of frank cases of the disease in school-boys who were exposed to the rather changeable weather of the last few weeks. Dr. Lambert called attention to the fact that pneumonia always remains local except in fatal cases. The pneumococcus can be discovered in the blood only within from twenty-four to forty-eight hours before death. Cases with a good prognosis invariably show no pneumococci in the blood.

Dr. Morris Manges said that if sufficient blood be taken for examination the pneumococcus will be found very frequently in the blood of pneumonia patients. Previous bacteriological examinations in this regard have been at fault because of errors of technic. Pneumonia seems still to fall best into the category of constitutional diseases with a local manifestation.

BOOK REVIEWS.

Transactions of the American Ophthalmological Society. Thirty-Seventh Annual Meeting, New London, Conn., 1901. Hartford. Published by the Society. 1901.

In contrast with the Transactions of the sister society, the American Otological, for the same year, these are of much greater value, not merely in the quality of the ordinary material, but also in the fact that they embrace two most desirable new features. These are, first, a report covering 40 pages "On the Supplementary Histories of Cases Recorded in the Transactions of the Society Prior to 1900;" second, a report covering 45 pages, "On Standards and Methods of Examining the Acuteness of Vision, Color-Sense and Hearing." This last report is most careful and exhaustive and is of great value and authority.

Two of the papers presented were unusually valuable in their sweep and interest. These were presented by Drs. de Schweinitz and Bull, the first on glaucoma, the second on metastatic choroiditis. The whole volume is up to the highest type of its class.

A Guide to the Microscopic Examination of the Eye. By Professor R. Greef, Surgeon, Ophthalmic Department, Royal Charity Hospital, Berlin. Translated from the Second German Edition by Hugh Walker, M.A., M.B., C.M. Price $1.25. P. Blakiston's Son & Co., Philadelphia.

This monograph of 171 pages appears to us to be well-nigh complete and perfect both in form, make-up and material. The paper has that soft tint which is much more restful to the eyes than the glaring white paper so generally used in this country. The type even has a most perfect character of its own. This volume contains all essential information for the most complete microscopical examination of every tissue of the eye. Three-fourths of the book are devoted to general considerations of the means of preparing and caring for the tissues, methods of fixing, hardening, embedding, staining; specific methods of staining; demonstration of definite substances, such as cholesterin and tissue elements. The second part of the book occupies the remaining fourth of it and studies in detail the cornea, iris and choroid, lens, zonula ciliaris, retina and optic nerve. For compactness and elegance of form and for concise yet full and thorough treatment of the subject, the book is a model.

Transactions of the American Orthopedic Association. Fourteenth session, held at Washington, D. C., May 1, 2 and 3, 1900. Volume XIII.

Since America has been the pioneer in orthopedic work, it follows that the transactions of her association representative of this department of surgery must always be of great interest and value. The association is to be cordially congratulated on presenting a volume of its own making which in every detail is the equal of its predecessors. The paper is pure, the type large and clear; the illustrations—particularly the photographic reproductions—are admirable.

The volume is introduced by an address of the President, Dr. Harry M. Sherman. It is an able plea for the furtherance of orthopedic instruction in our medical schools. In speaking of the far-reaching need of this, after citing the unhappy fact that with the exception of genito-urinary work orthopedics comes at the bottom of this list, only a little more than one-half of the colleges giving recognized orthopedic courses, he says: "It is not as a sentimentalist that I mention the child's age and his helplessness. It is because the acts committed on him when he is young and helpless reach out and affect him when he is neither. The old can get but a few years' benefit from any surgical procedure; the middle-aged may have only the last half of life made or marred by surgery. But for the child it is different. Success or failure is for life; it will tell for good or evil in the developing of mind and character."

While every paper presents points of interest, there are some which seem particularly progressive. Dr. Joel E. Goldthwait of Boston, in summarizing his conclusions on knee-joint surgery, says: "Operations upon joints need not be feared more than operation upon other parts." The general trend of opinion among the members is strongly adverse to forcible correction of the deformity in Pott's disease—the New York men in particular feel that they have demonstrated its futility. In discussing the treatment of abscesses of the joints, Dr. A. M. Phelps, after denouncing the "let-alone" method and describing the results obtained by establishing very free drainage and disinfection by pure carbolic followed by alcohol, closes with the following words, which must seem very reasonable to the general surgeon: "I believe that we, as orthopedic surgeons, have no right to violate established scientific surgical laws." These and many other papers make the Transactions of the thirteenth congress of very unusual interest and value.

ORIGINAL ARTICLES.

MALNUTRITION AS SHOWN IN CONGENITAL SYPHILIS.

BY CHARLES GILMORE KERLEY, M.D.,
OF NEW YORK.

A RECENT severe syphilitic infection in one or both parents results in either sterility or, if conception occurs, the death of the fetus. When there is a more remote infection or one in which the severity is less pronounced, perhaps as a result of the treatment, the pregnancy may go to term, the fruit showing marked evidences of disease; or, if the child be born apparently well, the characteristic signs of congenital syphilis appear in a month or two.

The so-called tardy hereditary syphilis, manifested by faulty development, and the well-known interstitial changes indicate a more remote infection on the part of the parents or their more successful treatment. The so-called "cured" syphilitics are the parents of tardy hereditary cases. When does the syphilitic poison in an individual completely lose its power, so that the offspring will show no signs of contamination? The answer is this: We can never promise a man or woman who has had syphilis that his or her children will be free from the disease.

Tardy malnutrition is the most remote manifestation in the offspring which tells us that the child has congenital syphilis. Syphilis is a cause of malnutrition in the early months of life, but it differs in no respect from the malnutrition associated with any other grave chronic disorder, and, as a symptom of diagnostic worth of early congenital syphilis, its value has been greatly exaggerated. When malnutrition is present in early cases, other pronounced signs are always present to explain the malnutrition. In older children, those of from three or four years to puberty, the case is different. Persistent malnutrition in the absence of apparently adequate cause and in spite of supporting treatment may mean congenital syphilis without any symptom other than malnutrition.

I have seen six cases of this nature in which the fathers of the patients confessed to having had syphilis. In three the diagnosis was further confirmed by successful antisyphilitic treatment. Two of these children were sister and brother, aged respectively five and seven years. They came under my care several years ago. Both parents were strong and vigorous. The father was forty-five, the mother thirty-three years of age; the family history was excellent. There had been no miscarriages. The patients were the only children. They had been fairly well as infants, no history of snuffles, of marked restlessness nor of rash. The heart and lungs were negative, the muscles were soft and poorly developed; the boy had adenoids. They were undersized, underweight, slight, frail children. They became tired easily, could not bear the cold, and their appetite was always poor. The father denied having had syphilis. They had been treated by several physicians, and had been systematically dieted, drugged, bathed, oiled, and aired. When they came under my care I continued this treatment for six months, because I did not know anything better to do. The results were negative. Again I questioned the father, who confessed to having had syphilis fifteen years before his marriage. He had passed through the secondary stage, had been treated abroad, and had been told that he was cured and that he might marry with safety. I changed the treatment at once; gave bichloride of mercury, $^1/_{80}$ grain, with iodide of potassium, 5 grains, three times a day. This change of treatment was followed by the most satisfactory results. In six months, under specific treatment, which was changed from time to time, the children became strong, active and well nourished, The mother, who remains ignorant of the nature of the trouble, has never quite forgiven me, because it was six months before I found the tonic her children needed.

A mother brought her nine-year-old son, at his (the son's) request, to see if he could not be made like other boys, who could play football, baseball and who could skate without having to sit down and rest every few minutes. The boy's father is a large, powerful man, weighing over 200 pounds. The mother is a strong, well-built woman and maintains that she is in perfect health. She had never had a miscarriage. The family history was negative, with the exception that the mother said that the father, who was absent, had had syphilis, and remarked that the question had never before been asked her. The boy weighed 63 pounds. He was of large frame, but of very poor muscular development. The heart, lungs, kidneys, and eyes were negative. The examination further revealed that fact that both epitrochlear glands were enlarged, which was the only evidence of syphilis other than malnutrition and general weakness. He was pale and complained of being chronically tired; his appetite was poor. He had been treated by diet, baths, iron, quinine, oil, etc., without benefit. I gave him bichloride of mercury $^1/_{60}$ grain, three times a day, but made no change in diet or in the habits of life. During the next four months he gained five pounds in weight. The average gain for a boy of this age for one year is six and one-half pounds. Under the bichloride, the appetite and the blood conditions im-

proved, and there was an increase in strength and endurance. To-day, one year after beginning treatment, he weighs 70½ pounds, and to all outward appearances is a perfectly well boy. My plan of treatment in his case for one month was bichloride, $^1/_{60}$ grain, three times a day, and one month's rest from treatment. In this case the infection of the father dated back twelve years before the boy's birth.

The three other children varied in age from four to seven years. Two of these were brother and sister. They were from one to two inches undersized and from two to four pounds underweight. They suffered from lowered vitality and were thin, pale and delicate in appearance. Heart, lungs and eyes of each were negative. The parents were in average good health. The two fathers confessed to having had syphilis, the infection antedating conception ten years or more in both. They had been treated, pronounced cured and told to marry. The children improved satisfactorily under treatment, which was discontinued after the improvement was noticed, and they passed from under my observation.

I require all of my cases of apparently-cured congenital syphilis to report every third month.

Given a family such as this, father and mother of average health and strength, with a negative family history, child or children "delicate," undersized and underweight, with lack of endurance, low vitality, indifferent food capacity, poor appetite, I add bichloride of mercury or iodide of potassium to the treatment, regardless of the social standing of the parents, and am usually gratified, but never surprised, at the satisfactory outcome.

I have learned to look with suspicion upon puny, delicate children of parents who have average good health, when there is no discoverable reason for the malnutrition, and who persistently resist well-directed hygienic and supporting measures.

THE NECESSITY FOR SANITARY SAFEGUARDS ON THE CENTRAL AMERICAN CANALS.

BY GEORGE A. SOPER, PH.D.,
OF NEW YORK.

A paper entiled "Sanitary Aspects of the Panama and Nicaragua Canals," by the present writer, published in Medical News, January 4, 1902, has brought forth a critical reply (Medical News, February 1, 1902) from one who does not agree that both routes present conditions particularly unfavorable to health and that the Panama line has some features which give it an advantage over its rival from the standpoint of hygiene. It was hoped that the paper would bring about a general discussion which would throw more light on the conditions which will be likely to obtain if a ship canal is built across the Isthmus, but, no further criticism being apparently forthcoming, it remains to review the remarks which have been offered.

At the outset the criticism is very sweeping, for its object is to discredit the author's information or the avowed purpose of the paper, which was to inquire from a disinterested standpoint into conditions which make for or against health in the countries and along the routes which are now under consideration. To this general charge no extended reply is necessary. In the preparation of the paper, every available source of information was carefully scrutinized and a very large number of official documents and records of unprejudiced observers were examined; the facts given represent what, in the author's view, were the most significant features of this evidence in condensed form. Finally, as to bias, the author is not and has never been connected in any way with either canal enterprise, while it is to be noted that the critic announces himself as former surgeon to the company which undertook to build the Nicaragua Canal in 1889.

One of the first points of criticism has to do with the precise meaning of the term "Isthmus of Central America." To quote the words of the critic, "The writer of the article referred to also shows a lack of precise knowledge of geographical as well as political lines by confounding Central America with the Isthmus." He then declares that "Isthmus" applies only to Panama. He seems to forget the Isthmus of Darien and the Isthmus of Tehuantepec and the fact that the whole of that narrow stretch of land between North and South America is in reality a great isthmus. There is the best of authority[1] for extending the term "Isthmus of Central America" to cover all the country between the land west of the Atrato River in Colombia and that part of Mexico which lies east of Tehuantepec. This is the sense in which the author has employed it.

Other exceptions taken by the critic concern the healthfulness of Central America and particularly of Nicaragua. The present writer believes that conditions in Central America are not favorable to settlers of Northern birth. The critic denies this and asserts that there are many beautiful and healthful spots where large foreign colonies have lived successfully for years. It is regretted that he has not strengthened his statements by giving definite facts and that his "large colonies" are not instanced. In the limited literature of the subject, it is stated that early Anglo-Saxon immigration met with disaster. Davidson[2] tells of two different parties of Scotch colonists who landed at Darien and met with great loss of life through disease. In recent times the Central American Republics have offered tempting inducements to foreign settlers, but without apparently attracting "large colonies."

Nicaragua, east of the Cordilleras, is mostly unexplored and inhabited only by wild Indians except on the immediate coast.[3] According to the census of 1892[4] the number of foreign-born

[4] Statesman's Year-Book, 1898, p. 797.

settlers in Nicaragua is 371, of whom 200 are Anglo-Saxons. Costa Rica, more favored in respect to population and distribution of wealth, had 792 Anglo-Saxon settlers[1] in the same year. The roads are reported as poor and the total length of railways in both countries in 1900 was 208 miles.

It is true that all climates from the torrid to the frigid are found between the lowlands and mountaintops of Central America, but it should be remembered that the climates which are available to foreigners who desire to settle permanently are only those which are reasonably accessible by railroads and navigable streams.

With respect to the health of the Maritime Canal Company's employees during their operations in Nicaragua, the critic declares with italic emphasis that carefully-kept medical records show that the death-rate among the employees at work along the route of the canal was seven-tenths of one per cent. Either this statement or the text of an official report[2] of the canal company to the United States Government is in error. Reference to these authoritative data shows that seven-tenths of one per cent. was the hospital death-rate from diseases which the Maritime Canal Company considered were peculiar to the country.

Inasmuch as the critic makes large capital of the fact that but little disease has occurred along the Nicaragua route, the reason for this apparent exemption may as well be stated. One of the Isthmian Canal Commissioners admirably explains the situation when he says: "The Nicaragua route is practically uninhabited and consequently practically no sickness exists there."[3]

And there is an equally good reason why the death-rate observed at the time of the Maritime Canal Company's work was low. The operations of the company extended from 1889 to 1893, but a Government report[4] declares that: "During this period of over three years comparatively little work was accomplished." The work actually done is stated on the Isthmian Canal Commission's authority to have consisted in a single-track railroad eleven and a third miles long, thirty-nine buildings, wharves and a pier, some sea dredging and canal cuttings, the latter aggregating less than two miles in length. In addition, the company reported that several miles of timber had been felled and some rock had been removed from the Machuca rapids.

This inventory indicates that very little dangerous work was attempted by the Maritime Canal Company, while every precaution against the introduction and spread of infectious diseases known to the promoters was undertaken.[5] Under the circumstances it is not strange that competent authorities should consider the health records of the company to have little bearing on the conditions which would probably occur were serious work on the Nicaragua Canal undertaken.[1]

To the present writer the principal sanitary dangers incident to the construction of a ship canal across Central America seem fairly evident. According to the belief of the day, epidemic diseases do not spring from the earth or air *de novo*. They have a specific origin and this is usually to be found in the secretions and offscourings of persons who are already ill. Air, soil and water may harbor mosquitoes and other vehicles of disease and may themselves act as carriers of bacterial poisons, but they are powerless to produce an epidemic of cholera, yellow fever or typhoid, for example, unless they become infected. How the first cases are imported to a new territory can easily be imagined. In a great mass of people there are always some who are suffering from mild forms or who are in ambulant stages of transmissible diseases. Among camp-followers and the adventurous idlers who travel with armies infectious diseases are universally common.

To complete either canal, from ten to fifteen and possibly twenty thousand men would have to occupy the line for eight or ten years. The laborers would be principally Jamaica negroes and Indians, unused to restraint and unfamiliar with the principles and practices of hygiene. All would have to be sheltered, fed, disciplined and doctored like so many soldiers.

Hygiene is the precaution which science offers to safeguard the health and lives of the men. The present writer believes that the methods of sanitation and health protection which are available to-day for such purposes are adequate, if properly applied, to avoid such terrible sacrifices of life as have been witnessed in times past. That there would be difficulty in applying the principles of hygiene in the effective manner demanded he thinks should not be denied. Any argument which tends to minimize our appreciation of the dangers incident to building a ship canal across Central America is liable to do the great harm of making more remote the chance that full and comprehensive preparations to meet the conditions will be made.

As compared with the Nicaragua route, the Panama line appears to the present writer to have some distinct advantages for health, among which the following may be mentioned: The Panama route has less length of swamp to be excavated, less total length and less rainfall; fewer laborers would be required and their greater concentration on the Panama route would permit the sanitary organization necessary for their protection to be more compact and complete and consequently more efficient.

Finally, the last question to which the critic has addressed himself, the permanent sanitary condition of the canal, lends to his argument a peculiar climax. His picturesque description of "the

Island of Nicaragua" and his prophecy that it will become "a favorite winter resort, fully as attractive and healthy as some of our West Indian Meccas for pleasure-seekers," are not convincing proof that the lake region is, as he asserts, "notoriously healthy."

The sufficient reason why the United States is to build a canal across the Central American isthmus is that such a waterway is desired for the safe and convenient passage of American ships. The study of the sanitary aspects of the two lines which the present writer has made leads to the conclusion that, while it is within the bounds of practicability to keep either comparatively free from epidemic diseases, the Panama route would entail less risk and less expense.

A REPORT ON THE USE OF ANTIPHTHISIC SERUM T. R.

BY EARL SPRAGUE BULLOCK, M.D.,

OF SILVER CITY, N. M.;

MEDICAL DIRECTOR, ST. JOSEPH'S SANATORIUM, SILVER CITY, N. M.; FORMERLY PATHOLOGIST AND PHYSICAL DIAGNOSTICIAN, U. S. GENERAL HOSPITAL FOR TUBERCULOSIS, FORT BAYARD, N. M.

A COMMUNICATION dated October 11, 1900, from John T. Milliken & Co., of St. Louis, Mo., was forwarded to the commanding officer of the United States General Hospital, Fort Bayard, N. M., through the office of the Surgeon-General, in which an offer was made to supply that hospital with their serum in sufficient quantity to make a test of its utility in the treatment of pulmonary tuberculosis. The only additional fact of interest in connection with this offer was a request from the manufacturers that the results "whether good, bad, or indifferent, be published."

Its administration was not compulsory and in all thirty-three (33) patients submitted to it. With two exceptions the cases were of the most favorable type, and all were classified as afebrile. Ten of these cases will not be reported, as in them the serum was discontinued within a day or two for reasons not attributable to it, the patients being discharged, etc. The remaining twenty-three (23) cases have been divided into four classes as follows: (1) Those in which the serum was discontinued on account of an apparently permanent rise of temperature produced; (2) those in which there was little or no change during the period of treatment; (3) those in which there was failure during the period of treatment; (4) those in which there was improvement during the period of treatment.

The case histories, which have been written as briefly as possible, will be detailed in accordance with this classification, a short summary being appended to each. The initial dose of 5 minims was increased at the rate of 5 minims a week until the maximum dose of 15 minims was attained. The plan of increasing the dose very gradually was adopted with the idea of mitigating, as far as possible, the very disagreeable reaction that occurs in the majority of cases at the end of the first five or six days. This reaction consists of a rise of temperature, malaise, headache, and various itching skin phenomena, urticaria, erythema, etc. But four so-called instantaneous reactions were observed during the experiments. These are most probably the result of the direct introduction of the serum into the circulation. They are extremely distressing, the principal phenomena manifested being flushing, a feeling of fulness in the head, itching, pain in the lumbar region and intense dyspnea. Fortunately they are very ephemeral, passing off in a few moments.

On April 4, 1901, the conclusion was reached that the serum was either harmful or entirely negative, and the experiments were all discontinued on this date, especially with the idea of observing the effect of its withdrawal. And, it may be added, in no case did the withdrawal have any effect whatever upon the subsequent course of the disease. In no instance has a request for its further use been received.

1. *Cases in which the serum was discontinued on account of an apparently permanent rise of temperature produced.* These cases were six in number, as follows:

Case I.—Admitted January 6, 1900. Aged thirty-nine. Family history negative. Disease subsequent to malaria during the campaign in Cuba. Not a tuberculous type. Tubercle bacilli present. Lesion consisted of infiltration of both apices. Patient was received in good condition, and remained so during the entire period of observation. On October 17, 1900, injections of serum were begun. At the end of a few days the patient exhibited marked rise of temperature at night, from 101° to 102° F. The evening fever continued until the injections were stopped on November 5, 1900. Following the withdrawal of the serum, the temperature resumed previous range, from subnormal to 99.6° F. Patient was discharged February 17, 1901, in a slightly better condition than upon admission, but with tubercle bacilli still present and pulmonary status practically unchanged. Prognosis favorable.

Conclusion.—The prompt drop in temperature following the withdrawal of the serum makes it very probable that the serum was the cause of the rise. The continued elevation of temperature was considered sufficient cause for discontinuing the treatment.

Case II.—Admitted July 10, 1900. Aged twenty-six. Family history negative. Not a tuberculous type. Disease secondary to typhoid fever. Admitted in bad condition with gross emaciation. Tubercle bacilli present; fever, etc. Lesion consisted of consolidation of the right apex, infiltration of the right lung anteriorly and left upper lobe. Following complete rest in the infirmary the temperature dropped below the febrile point, and simultaneously the general pulmonary condition began to improve. On October 17, 1900, injections of serum were begun and continued until October 24, 1900. Most aggravated erythema and urticaria associated with high

temperature (102° to 103° F.) followed the second injection, and as these symptoms continued without amelioration the serum was discontinued on the date mentioned. Several weeks passed before the evening temperature fell below the febrile point and the previous condition of affairs again obtained. Patient was discharged April 22, 1901, in very good general condition. The lesion had advanced in the upper lobes and cleared at the base. Prognosis favorable.

Conclusion.—Unquestionably the serum was accountable for the disagreeable symptoms produced, and on account of the apparently permanent rise of temperature, etc., its further use was not considered justifiable.

Case III.—Admitted August 7, 1900. Aged twenty-seven. Family history negative. Tuberculous type. Disease contracted while on duty on United States transport as nurse. Patient was received in fair condition and without fever. Tubercle bacilli present. Lesion consisted of consolidation of both apices, bordered by infiltration involving the remainder of both upper lobes. The general condition gradually improved until the injections of serum were begun on October 17, 1900. Urticaria and fever followed the second dose, and as the fever continued unabated the serum was discontinued one week later, and the disappearance of symptoms followed promptly upon its withdrawal. Patient at present is considerably improved. The lesion is free from signs of activity and consolidations have resolved. Prognosis favorable.

Conclusion.—The same reason, apparently permanent rise of temperature, which dictated the discontinuance of the treatment in the preceding cases held good also in this, though no permanent injury resulted, previous conditions being quickly re-established.

Case IV.—Admitted August 11, 1900. Aged thirty-one. Family history negative. Not a tuberculous type. Disease secondary to dysentery contracted in the Philippine Islands. Upon admission the patient was in good general condition and presented a small area of disease—infiltration of the right apex—which was, however, associated with great activity, enormous numbers of tubercle bacilli and a marked febrile tendency. He never did well, and on October 17, 1900, injections of serum were begun. As the temperature immediately became still further aggravated it was withdrawn five days later. Disease rapidly progressed, and patient was discharged with an unfavorable prognosis, being readmitted a few months later only to die in a short time of intestinal tuberculosis.

Conclusion.—Serum treatment was, of course, not indicated in this case. It was only used at the earnest solicitation of the patient, and the exacerbation of temperature caused was sufficient reason for its prompt withdrawal.

Case V.—Admitted September 3, 1900. Aged twenty-three. Family history positive. Disease followed a severe cold. Not a tuberculous type. Was received in good general condition. Afebrile. Tubercle bacilli present. Lesion consisted of slight infiltration of the right apex. Improvement began at once and continued until injections of serum were begun October 17, 1900. Within a day or two the temperature began to exhibit a constantly increasing tendency, and on this account it was withdrawn November 13, 1900. A day or two later the temperature resumed its former range, subnormal to 99.2° F. Patient was discharged improved with bacilli still present, January 5, 1901.

Conclusion.—The exacerbation of temperature was doubtless the result of the serum and dictated its prompt withdrawal.

Case VI.—Admitted October 2, 1900. Aged twenty-eight. Family history negative. Received in poor general condition. Tubercle bacilli present. Lesion was consolidation of the right apex and infiltration of the remainder of the right lung anteriorly and of left apex. In general the course of the disease has been progressive since admission, with occasional periods of fever. On October 17, 1900, injections of serum were begun and discontinued two weeks later on account of an apparently permanent rise of temperature produced. It was not until six weeks had passed that the temperature resumed its former range, below 100° F. at night. The patient is still under observation; the lesion has markedly increased, and the prognosis is unfavorable.

Conclusion.—The serum is of course not accountable for the steady retrogression in this case, it was withdrawn solely on account of the exacerbation of temperature produced.

2. *Cases in which there was little or no change during the period of treatment.* There were five cases in this class as follows:

Case VII.—Admitted February 5, 1900. Aged thirty-one. Family history negative. Not a tuberculous type. Disease resulted from exposure during the campaign in Porto Rico. Patient received in good condition. Lesion consisted of slight infiltration of both apices. Tubercle bacilli present. Afebrile. Injections of serum were begun October 17, 1900, and discontinued April 4, 1901, to observe effect of withdrawal. Shortly after the injections were commenced the temperature fell to normal, where it has remained since, the withdrawal of the serum on April 4, 1901, having no effect whatever. During the use of the serum the right apex consolidated and subsequently resolved. The pulmonary status is now practically what it was on admission, though the general condition is much better. Tubercle bacilli never disappeared. Patient is still under observation, and ultimate recovery is anticipated.

Conclusion.—As the treatment manifestly had no influence in preventing consolidation, it is not reasonable to attribute to it the subsequent resolution of the consolidated area. Both this and a fall in temperature to the normal are so frequently observed as the result of non-specific treatment that they must needs occur much more frequently than they do to be attributed to the action of the serum.

Case VIII.—Admitted May 14, 1900. Aged twenty-eight. Family history negative. Disease began insidiously at Jackson Barracks, New Orleans. At the time of admission initiatory symptoms had mostly disappeared, and it required the tuberculin test to substantiate the diagnosis of tuberculous infiltration of the right apex. Patient was apparently in perfect health. Following the tuberculin test the temperature became 99° F. at night. Bacilli, cough, and expectoration did not develop until November, 1900. On February 18, 1901, injections of serum were commenced. Within a few days the evening temperature became normal and a drowsiness in the late afternoon developed. Otherwise the status remained unchanged. April 4, 1901, the serum was withdrawn, with no effect whatever except the relief of the drowsiness mentioned. Bacilli are still present. Prognosis is good.

Conclusion.—In regard to the drop in temperature during treatment, the remarks which closed Case VII. seem equally as applicable to this. The negative effect of the withdrawal of the serum apparently substantiates this opinion.

Case IX.—Admitted June 26, 1900. Family history negative. Tuberculous type. Disease secondary to malaria contracted in Porto Rico. Though the lesion was comparatively insignificant, infiltration of right apex and posterior base, the general condition was very poor at the time of admission. Though classed as afebrile, there has always been a tendency to fever from slight causes. Tubercle bacilli constantly present. The general condition improved slightly, and October 17, 1900, injections of serum were commenced. Following a very severe instantaneous reaction January 14, 1901, patient refused further treatment. No objection was made, for latterly the weight had diminished and evening temperature was persistently over 100° F. Following the withdrawal of the treatment patient gradually improved and regained condition which existed previous to the beginning of the injections. Prognosis is not favorable.

Conclusion.—The effect of the serum in this case has been interpreted as negative; for, the history has been one of alternating slight improvement and retrogression, and it would not, of course, be reasonable to attribute to the serum what had already occurred several times without it in the same case.

Case X.—Admitted July 6, 1901. Aged thirty-six. Family history positive. Full-blooded negro. Not a tuberculous type. Disease secondary to malaria and dengue fever in the Philippine Islands. Patient was received in excellent condition. Afebrile. Bacilli present. The lesion was slight infiltration of both apices. There has been no change in condition since admission. Injections of serum were begun February 18, 1901, and continued until April 4, 1901, when they were discontinued to observe the effect of withdrawal. No apparent change resulted, and patient states that he does just as well if not better without it. Prognosis very good.

Conclusion.—Though the period of treatment was short it was entirely without effect.

Case XI.—Admitted January 21, 1901. Family history negative. Not a tuberculous type. Disease secondary to malaria contracted at Washington Barracks. When admitted patient was apparently in the best of health and has remained so. He was without fever. Bacilli present. The lesion was slight infiltration of the right apex. He received the serum from February 1, 1901, to April 4, 1901, when the treatment was discontinued to observe effect of withdrawal. Patient states that he never missed the serum in any way. Bacilli persist and condition has not changed appreciably. Prognosis very good.

Conclusion.—As in the previous case the result has been interpreted as negative.

3. *Cases in which disease progressed during the period of treatment.* There were six cases in this class as follows:

Case XII.—Admitted August 13, 1900. Aged twenty-five. Family history negative. Not a tuberculous type. Disease secondary to malaria and dysentery in the Philippine Islands. On admission general condition was poor. The lesion was active infiltration of the left lung and right apex. The case was afebrile, and bacilli were present. At first general and pulmonary condition rapidly improved. October 17, 1900, injections of serum were begun. During the period of treatment the patient slowly failed, losing in weight and the temperature exhibited a gradual, but constantly increasing tendency. On this account it was withdrawn January 1, 1901. Almost at once the temperature fell to normal and improvement again began and continued up to the time he was discharged at his own request April 3, 1901.

Conclusion.—The retrogression that commenced simultaneously with the use of the serum and which promptly ceased upon its withdrawal can have but one interpretation; viz., the serum proved injurious.

Case XIII.—Admitted November 14, 1899. Aged thirty-two. Mother died of pulmonary tuberculosis. Tuberculous type. Disease secondary to malaria contracted during the Cuban campaign. At the time patient came under observation general condition was poor and lesion consisted of infiltration of the right upper lobe and left apex. Bacilli present. Afebrile. From the first the patient rapidly improved, and within a short time the temperature became normal. He received injections of serum from March 25, 1900, to May 1, 1900. At the end of the first week a very severe reaction occurred. As long as the treatment continued the evening temperature never again became normal; on the contrary, it showed a constant tendency to increase. During the third week there also developed aggravated intestinal symptoms with severe pain an hour or two after eating, nausea, and anorexia. Weight also diminished. After the discontinuance of the injections, all these symptoms ceased, the temperature again became normal, and general progress towards health was resumed. The patient is still

under observation and has improved very much, though bacilli associated with physical signs of a slight infiltration of the right apex persist. Prognosis good.

Conclusion.—As in the previous case the retrogression which heralded the initiation of the treatment and the prompt disappearance of symptoms which followed its withdrawal can only be interrupted as a result of the treatment.

Case XIV.—Admitted March 3, 1900. Aged forty-three. Family history negative. Not a tuberculous type. Disease secondary to exposure in Alaska. When received patient was in fair condition and lesion was consolidation of both apices, with an old dry cavity posterior on left side. Case was afebrile. Bacilli present. The disease was apparently arrested at the time of admission, though the patient was about twelve pounds under weight. Shortly after admission improvement began, with disappearance of bacilli from the sputum, and was maintained up to the time patient began to receive the injections on October 17, 1900. Almost at once the temperature manifested a constantly increasing tendency (101.5° F. to 102° F.). There was also a great increase in cough and expectoration. Bacilli reappeared and became a constant feature of the sputum, and the lesion began to extend. The withdrawal of the serum on December 26, 1900, was followed by a cessation of symptoms. The temperature again became normal. Signs of activity over the lesions disappeared and patient improved, being discharged February 8, 1901, in somewhat better condition than on admission, though bacilli persisted.

Conclusion.—The treatment excited an apparently quiescent disease. The case is of unquestionable significance in the light of the fact that bacilli had been absent from the sputum for some time previous to the beginning the treatment.

Case XV.—Admitted March 1, 1900. Family history negative. Not a tuberculous type. Disease secondary to exposure while in the Philippine Islands. Patient in good condition when admitted. Afebrile. Bacilli present. Lesion was infiltration of both apices. The patient, who was one of the physicians on duty at this hospital, illustrated the type of the disease that is complicated by asthma. He received injections of serum from July 26, 1900, to September 26, 1900. During the treatment the evening temperature became 99.6° F.; weight diminished, and the patient did not feel so well. The treatment was discontinued at his request. The temperature returned to normal after the withdrawal of the serum, the weight improved: etc. He was discharged November 27, 1900, in somewhat better health, but with the lesion practically unchanged and bacilli still present. Prognosis favorable.

Conclusion.—The opinion of the patient in this case is entitled to consideration. He requested that the treatment be discontinued; for, he said, "Its effect was either negative or it caused the exacerbation of temperature."

Case XVI.—Admitted November 20, 1899, Aged twenty-four. Family history positive. Not a tuberculous type. Disease secondary to typhoid fever during the campaign in Porto Rico. Patient was in good condition and lesion consisted of infiltration of the right apex and base. Afebrile. Tubercle bacilli present. General health and pulmonary condition rapidly improved, and he remained in excellent condition until the fall of 1900, when he began to fail slightly. October 17, 1900, injections of serum were begun and continued until March 1, 1901. During the treatment the right apex consolidated and excavated. The left apex became actively infiltrated. As the treatment was manifestly without influence in preventing or controlling the extension of the lesion it was withdrawn on the date mentioned. Some time later the patient again began to improve, and at present the disease is apparently arrested and the general condition improving. The prognosis is favorable.

Conclusion.—Failure had begun previous to the initiation of the treatment and continued in spite of it. In consequence the effect in this case has been interpreted as negative.

Case XVII.—Admitted January 25, 1901. Aged twenty-two. Family history negative. Not a tuberculous type. Disease followed exposure in the Philippine Islands. When admitted was in good condition. Lesion consisted of infiltration of the right upper lobe. Afebrile. Tubercle bacilli present. He received injections of serum from February 18, 1901, until his discharge April 5, 1901. Previous to the beginning of treatment patient did not show any tendency to improve, on the contrary, he lost weight and the lesion progressed. During the period of treatment the right upper lobe consolidated.

Conclusion.—The effect of the serum was considered negative, as the patient exhibited a tendency toward retrogression before it was begun, as well as during the period of its administration.

4. *Cases in which there was an improvement during the treatment.* There were six cases in this class as follows:

Case XVIII.—Admitted May 31, 1900. Family history positive. Disease secondary to malaria in the Philippine Islands. Patient was received in good condition. The lesion was consolidation of the right apex and infiltration of the left. Afebrile. Tubercle bacilli present. In general it may be said that there has been a slow but constant improvement in this case, both in general and pulmonary condition. The serum treatment was begun October 17, 1900, and discontinued April 4, 1901. During the period of its use the improvement continued the same as previously, apparently being neither accelerated nor retarded by the treatment. Some time after the injections were begun the temperature fell to normal, where

it has remained since. Patient states that he is doing fully as well without the serum. Bacilli persist. Prognosis favorable.

Conclusion.—In view of the fact that the rate of improvement continued the same both before and during the period of treatment the result has been interpreted as negative.

Case XIX.—Admitted July 10, 1900. Aged thirty. Negro (half-blood). Family history unknown. Disease followed exposure in the Philippine Islands. At the time of admission was in very good condition considering an advanced stage of pulmonary and laryngeal disease. The lesion was consolidation of the right upper lobe with large dry cavity in this area. Vocal cords were ulcerated. Afebrile. Tubercle bacilli present. He improved from the first and just before injections of serum were begun on October 17, 1900, examination showed him to have regained his normal weight and to be in very good general condition. The ulcerations in the larynx had healed, though destruction of the cords had resulted in almost complete aphonia. The improvement in pulmonary condition was no less marked, the consolidated area had resolved, cavity healed and disease consisted of infiltration of right upper lobe and left apex. Treatment was discontinued November 6, 1900, at which time the patient was discharged at his own request. Condition at this time had not changed since previous examination.

Conclusion.—Though the period of treatment was very short the case has been included not only because it is of much interest apart from the subject of antiphthisic serum T. R., but also because the temptation to draw attention to another feature cannot be resisted. If the treatment with serum had been begun at the time of admission, the conclusion would have been almost inevitable that the serum influenced or achieved the remarkable result.

Case XX.—Admitted November 26, 1900. Aged thirty. Family history negative. Tuberculous type. Disease followed exposure in the Philippine Islands. On admission was in good condition. Lesion was infiltration of the right apex. Afebrile. Tubercle bacilli present. Improvement began at once and has continued to date. Injections of serum were commenced December 20, 1900. During February, 1901, cough and expectoration ceased and have since been absent. On March 1, 1901, the treatment was discontinued at the request of the patient as he had recently lost a few pounds in weight. At the present time, with the exception of the presence of signs of non-active infiltration of the right apex, and being a few pounds under weight, the patient is apparently well. He states that he has done fully as well without the serum.

Conclusion.—The result has been considered negative as the improvement anticipated the treatment and was maintained after its withdrawal. The cessation of cough and expectoration is frequently observed at this hospital in the absence of specific medication.

Case XXI.—Admitted October 11, 1900. Aged thirty-six. Family history negative. Not a tuberculous type. Disease began insidiously in the Philippine Islands when patient was much debilitated by the climate. Patient was received in very good general condition, and the lesion consisted of slight infiltration of the right apex. Afebrile. Tubercle bacilli present. Improvement and change in character of the sputum began at once and within a few days after the injections were begun, October 17, 1900, bacilli disappeared from the sputum, and have since been absent. The temperature, however, remained unchanged, averaging 99.2° F. at night. April 4, 1901, the treatment was discontinued to observe effect of withdrawal. Since the injections were stopped the status of the case has remained unchanged. Prognosis favorable.

Conclusion.—The result was considered negative for the same reason applied in the previous case.

Case XXII.—Admitted October 2, 1900. Aged twenty-seven. Family history positive. Not a tuberculous type. Disease followed exposure in the Philippine Islands. Patient was received in good condition. Lesion was slight infiltration of both apices. Afebrile. Tubercle bacilli present. Improvement began at once and continued up to the time of discharge, December 6, 1900. October 17, 1900, the injections were begun and continued as long as patient was under observation, at which time, though bacilli persisted, cough and expectoration had almost ceased. General condition was normal. Prognosis very favorable.

Conclusion.—The improvement was continued at the same rapid rate after the injections were begun as before, and, in consequence, the treatment was considered negative.

Case XXIII.—Admitted August 21, 1900. Aged twenty-one. Family history negative. Tuberculous type. Disease secondary to pleurisy in the Philippine Islands. Received in good condition with consolidation of the right apex and slight scattered infiltration of the remainder of the right lung anteriorly. Afebrile. Tubercle bacilli present. Improvement in general and pulmonary condition began shortly after admission, and has continued to date. October 17, 1900, the injections of serum were begun and continued until April 4, 1901. During the treatment the temperature, which had previously averaged slightly above normal at night, fell to normal and the bacilli disappeared from the sputum. The patient now enjoys very good health and is classed as convalescent, the withdrawal of the serum apparently not having influenced the subsequent course of the case in any way.

Conclusion.—The effect of the treatment was considered negative for the same reasons as in previous cases in this class.

Summary of Class 1. In this class the serum was discontinued on account of the apparently permanent rise of temperature produced. The elevation of temperature continued as long as the serum was used. In a disease in which one of the

first objects of treatment is maintainance of an approximately normal temperature, an agent which manifestly causes a rise cannot, of course, be tolerated. Seemingly, in this class, there was an idiosyncrasy against the serum.

Summary of Class 2. In these, in which little or no change occurred during the treatment, the action of the serum was negative. The cases illustrate that chronic type of pulmonary tuberculosis in which changes either for better or for worse are very slow and periods of improvement and retrogression are often encountered, but which are for the most part stationary. The treatment was obviously without effect.

Summary of Class 3. In at least three cases, viz., XII., XIII., and XIV., there is every reason to believe the serum to have been positively detrimental. In the cases mentioned the period of failure dates from the beginning of treatment and ceased with its withdrawal. In Case XV. it is at least probable that he serum caused the rise of temperature, and in the remaining two cases it was apparently negative.

Summary of Class 4. In the six patients composing this class, in which improvement occurred during the treatment, we are not inclined to attribute it to the action of the serum; for, taking the same number of equally favorable cases, the results obtained without any specific medication will be fully as good. This has been demonstrated at this hospital, as may be seen by reference to the Annual Report.

Every effort has been made to be perfectly fair in the recording of these experiments, and in submitting this report I feel that this has been accomplished.

As has been seen, the patients who received the treatment were, with few exceptions, all very favorable indeed, and excluding those in whom there is every reason to think the serum positively injurious, we see illustrated exactly what occurs during a limited period of non-specific treatment; viz., in a certain proportion of cases there is improvement, in others the condition remains stationary and in still others there is retrogression.

In my opinion the results obtained with this treatment are nearly comparable with those obtained without it, and for this reason I believe that those who have spoken favorably of this agent have unwittingly interpreted what occurs naturally as a result of proper hygenic surroundings in such a large proportion of tuberculous cases as the effect of this serum.

In using one therapeutic agent exclusively in the treatment of any self-limited disease, and pulmonary tuberculosis is often that, it is very easy to ascribe as the result of treatment what occurs naturally in a proper environment.

Hereditary Cerebellar Ataxia.—In the March number of the *Journ. of Nervous and Mental Disease*, H. T. Patrick gives a critical résumé of reported cases of this rare condition. He holds that there is no such disease entity and that what is so designated is a form of Friedreich's disease.

SIMPLE TRAUMATIC SYNOVITIS OF THE KNEE.[1]

BY WILLIAM S. THOMAS, M.D.,
OF NEW YORK;
SURGEON-IN-CHIEF, OUT-PATIENT DEPARTMENT, ST. LUKE'S HOSPITAL.

This common condition is so often either neglected or carelessly treated that I have felt justified in bringing it to your attention, although the subject may appear trivial beside the surgical topics of major interest which crowd medical literature to the exclusion of such humble, though practical, subjects as this. But time and the usefulness of patients, to say nothing of their comfort, are sacrified to perfunctory attention to these cases, which may drag along for months, now better, now worse, unless treated correctly, but, above all, thoroughly.

The term "simple traumatic synovitis of the knee" applies to a large class of cases following injury to the joint. It is chosen as a name because it refers to the cause of the condition present and excludes cases of bacterial origin and such complications as free bodies in the joint or loosened cartilages.

Among 150 patients treated in St. Luke's Hospital in the surgical clinic for the results of injuries to the knee, more than one-third (54) had simple traumatic synovitis. The records of these cases form the basis of this paper.

The typical case is met with in the young male. He limps in with extended knee, seldom using a cane, and tells of a wrench or bruise received several days or weeks before. The pain at the time of injury was severe, but not approaching the agony of a loosened semilunar cartilage or locked floating body. Since the accident he has had a varying amount of swelling about the knee and moderate disability, most noticeable on climbing stairs. On arising in the morning the stiffness and disability have been severe, but with moderate use the joint has limbered a little. It is this easing of the symptoms from time to time which has caused the patient to look upon his trouble as a slight sprain, soon to wear off; but the continuance of symptoms, with increase after the slightest knock or twist of the knee, has finally brought him to the doctor.

The joint is seen to be swollen with serous effusion, and is slightly tender on firm pressure everywhere, with perhaps one point especially so over the site of a bruised spot or stretched ligament. Full extension is possible, but flexion to a right angle is painful, and the limp is due more to the voluntary checking of flexion than to any pain of joint contact. The subjective symptoms may be of such moderate severity that the patient will demur when told that it will be necessary for him to wear a splint for many days and perhaps for weeks.

Pathology.—The changes in the course of a simple traumatic synovitis of the knee do not differ materially from those met with in other soft tissues. At first there is hyperemia followed by swelling and exudation of fluid both into the

[1] Read before the Medical Society of the Alumni of St. Luke's Hospital, Dec. 13, 1901.

membrane itself and into the articular cavity. The swelling is greatest about the loose folds in the ligamenta mucosa and alaria, which overlap the cartilages, their redness contrasting strongly with the pearly whiteness of the latter. Under the microscope there is seen to be much cell exudation into the perivascular spaces, with swelling and softening of the connective tissue by the extravasated fluid. The dilated capillaries occasionally give way and cause minute extravasations of blood to occur. The leucocytes escape into the substance of the membrane itself, and also penetrate between the endothelial cells and reach the articular cavity. The endothelial cells appear to multiply with unusual rapidity, and are cast off from the surface in considerable numbers.

In the earliest stages the synovial fluid is simply increased in quantity, but as the inflammation progresses the normal secretion is mingled with serum in varying proportions and afterward with fibrin and with red and white corpuscles. At first the fluid is clear, but later it becomes cloudy, opalescent or blood-stained. In cases in which the traumatism has been severe there are considerable extravasations of blood into the joint. This blood usually remains fluid owing to its admixture with the serum and synovia, as well as because of the smooth endothelial lining with which it is in contact. When the process undergoes resolution, the exudation ceases, the vascularity subsides, and the exuded fluid is absorbed. Extravasated blood delays resolution by its presence.

When the synovitis is not properly treated and drags along for months, there is little hyperemia, but a good deal of swelling and finally thickening from proliferation of fibrous tissue in the membrane. In these long-standing cases the fluid is clear and consists chiefly of serum, which may contain small shreds of fibrin or melon-seed bodies.

Etiology.—More than two-thirds of the cases were in males, their habits and occupations being of course to blame. Except at the extremes of life, age has apparently little to do with the liability to traumatic synovitis, since in this series of cases, at least, the number occurring in each decade of life was about the same. Children in arms are naturally less liable, and in the aged no doubt fractures of the lower extremity often result from injuries which might have caused but a traumatic synovitis in a younger person.

The violence which causes a simple effusion into the knee-joint is about twice as often direct as indirect, and it is surprising how mild are some of the cases in which the force has been great and what severe lesions may follow seemingly trivial injuries about the joint. In the excitement of a game or trolley-car accident, the initial traumatism to the knee may have passed unnoticed, while, again, it is common to see severe abrasions or ecchymoses about the knee without any effusion into the joint. In these cases the direction of the blow or the padding of soft parts has preserved the synovial membrane from injury.

The commonest form of indirect violence causing these effusions is a sprain about the internal aspect of the joint. These sprains are usually sustained by forcible abduction of the leg while the knee is partly flexed, or by outward rotation, both of which are checked by the internal lateral ligament. Sprains of the coronary ligament, especially the internal, may cause a general synovitis without being severe enough to allow a displacement of the semilunar cartilage. In cases of synovitis after a sprain, the tender spot over the stretched or torn fibers of a ligament may persist long after the effusion into the joint has disappeared.

Symptoms.—The subjective symptoms appear mild, as a rule, when the size of the knee-joint and its burdensome work are considered. As a matter of fact, the patients in this series of cases presented themselves for treatment on a average of eleven days after the beginning of symptoms, and then it was for the relief of disability rather than of pain that they applied, and oftener on account of the long continuance of symptoms than of their severity. The disability is noticed most when attempting to climb stairs and the stiffness and feeling of weakness become urgent when the patient attempts to walk more than a short distance. As for actual pain, the rule holds good which says: "Joint inflammations of bacterial origin cause pain which is increased with movement of the joint, while in traumatic forms the reverse is often the case. When the patient moves about the pain subsides, but it recurs on resuming movement after a considerable rest."

Tenderness on pressure over the synovial membrane everywhere, but emphasized over some point of contusion or sprain, is the rule, but has its exceptions. There is no noticeable tenderness, general or localized, in many of the milder cases. Here the point of sprain may be inaccessible to palpation. Extreme tenderness over the whole distended capsule is not found in simple traumatic synovitis, but occurs in the graver forms of bacterial origin. The greatest tenderness and the greatest pain in the simple cases occur when the amount of effusion is large and the joint capsule excessively distended.

Objective Symptoms.—Inspection shows the contour of the joint to be changed by the presence of the effusion into the capsule. The shape assumed is the same in knee-joint inflammations of whatever nature so long as the lesion is confined to a serous synovitis. The swelling is greatest in front, in the synovial pouches, which extend under the vasti muscles to a level of two inches or more above the patella on either side. There is also bulging of the mass of fat on either side of the patellar tendon. The patella itself is raised from the condyles by the fluid in the joint when the leg is extended, and the familiar symptom of floating is produced. Fluctuation of the joint is obtained when there is enough fluid pres-

ent to float the patella. But there may be so slight an excess of fluid as not to raise the patella unassisted and yet the presence of which it is important to determine for the sake of correct diagnosis and treatment. This is accomplished while the knee is extended by grasping the thigh just above the patella, so as to force down under the patella from the upper pouches whatever fluid may be contained in them, when the patella, struck over its center by the end of a finger, will be felt to knock against the condyles and produce the well-known patellar tap. J. P. Fiske (*Med. Rec.*, Vol. LIII., p. 376) describes a method, now much used, of determining the presence of small effusion into the knee-joint. The patient stands with extended knee, bending forward at the hips, with each hand resting on the anterior surface of the thigh at about its middle. The rectus femoris is thus relaxed and any fluid present settles behind the patella. The characteristic tap against the condyles of the femur is then obtained by a smart rap against the center of the patella. In the cases in which this procedure elicits the tap, the other side should be examined in the same way, for if there be enough fat below the patellar tendon to make it appear to float a little, the condition will be found to be symmetrical. In passing it may be well to say that both knees should always be examined, as there are several conditions causing symmetrical effusion into the joint.

Measurement of the circumference of the joint will show it to be one-quarter of an inch to two inches greater than that of the sound knee, according to the amount of effusion present. The measurement should be made at the lower and upper edges of each patella, for there is no little normal variation in the length of patellar tendons. When the tendon is unusually long, the effusion will raise the lower margin and give a greater increase here than above. Measurement of the circumference is a comparatively rough test, but is used from time to time to determine the increase or decrease in the amount of effusion. The color of the skin remains unchanged in these cases, even when the swelling is considerable.

The true involuntary spasm occurring in tuberculous disease is absent, and the joint may be fully extended without pain. Indeed, many of these patients naturally keep their leg in a position of full extension and I have never seen one of them carrying his knee flexed beyond twenty degrees. At any rate, it is very rarely that the fully-extended position gives discomfort. Flexion beyond a right angle is seldom permitted, even in cases with but a small effusion, and when the joint capsule is much distended flexion may be limited to a few degrees.

Passive motions may be carried further than active motions, if the examiner is gentle and has the patient's confidence, because of the disturbance which active motion causes in the joint by reason of the intimate connection of the neighboring tendons with the capsule.

We are constantly informed that the position of greatest ease to any inflamed joint is one of more or less flexion, but I believe that in the case of the knee-joint this statement is misleading, and that it is true only in such cases, for example, as tuberculous arthritis, in which there is spasm of the muscles of thigh and leg, or a mechanical derangement to interfere with full extension. If this be true, its practical bearing upon the treatment will be seen to be important. Atrophy of thigh and calf from disuse of the muscles is usually present after the first two weeks, but is never prominent. The body temperature is normal.

Course.—The average duration is about five weeks under immobilization in a well-marked case. Without treatment the course is much more protracted, and even after apparent cure many cases tend to recur persistently without being really chronic. This tendency to recurrence is a strong incentive to careful attention and intelligent treatment. There is usually a mechanical reason over and above further traumatisms, for repeated attacks. Sometimes lax ligaments may be to blame; again a more or less permanently stretched capsule, with poor support from weakened muscles, may be the underlying condition. The usual course seems to be shorter in children under twelve and longest in men who refuse or neglect treatment. Twelve days is a short time for a simple traumatic synovitis of the knee to last, but six months is not an unusually long time. The tendency to the formation of adhesions seems to be much less than is the case in some other joints,—notably the shoulder.

Diagnosis.—After having ruled out the presence of a misplaced semilunar cartilage by the history and by palpation along the edge of the articular surface of the tibia, the remaining conditions to be excluded in making a diagnosis of simple traumatic synovitis of the knee are as follows: Tuberculosis, rheumatism, gonococcic infection, syphilis, hematoma, "quiet effusion" of Bennett, hysterical joint.

There can be no doubt that some cases of tuberculous arthritis of the knee begin as a simple traumatic synovitism, but just when the invasion by the bacilli commences it is hard to determine. When true spasm intervenes, soon followed by increased atrophy of thigh and calf, with heat about the joint and afternoon pyrexia, the diagnosis will be clear. Morphological and biological examination of the effusion in obscure cases, or even the tuberculin test, may be called for.

In acute rheumatism there are fever, local redness and great tenderness, with a rheumatic history and probably involvement of other joints. In the chronic forms of rheumatism there are apt to be more ankylosis with changes in structures other than the synovial membrane and a rheumatic history together with the age of the patient to guide one. Joint crepitus is common in these cases. In a patient of the rheumatic diathesis a long-continued traumatic synovitis of the knee may give more trouble in damp weather and call for antirheumatic treatment.

The absence of urethritis will exclude the presence of a gonorrheal synovitis, but what is apparently a simple traumatic case occurring in a patient with specific urethritis should be treated as though it were of the more serious nature, and its course will soon demonstrate its true character.

The syphilitic knee of the secondary stage will be less apt to confuse one than the synovitis with effusion occurring in congenital syphilis as seen in children; but here the condition is regularly symmetrical and there will probably be a specific history.

Hematoma of the knee-joint follows a more severe grade of injuries than those usually the cause of simple synovitis. In large hemorrhages there will be clotting and a boggy feel, instead of the clear fluctuation, and in two or three days ecchymoses will appear in the skin. The hysterical joint, of course, shows no effusion. W. H. Bennett, in the London *Lancet*, describes a condition which I have never recognized. It is a "quiet effusion into the knee-joints occurring in women and young girls" which is always bilateral and is seen at puberty or at the menopause or in connection with menstrual difficulty. I have never seen so-called idiopathic synovitis of the knee occurring after exposure to cold and wet, though described by many writers, among them Billroth.

Treatment.—The remedial measures are mainly mechanical. Rest, complete or partial, counts for more than do all other means combined, but it is often discontinued too soon. In these cases of simple traumatic synovitis of the knee it is certain that unless the symptoms are unusually severe, little is to be gained by *absolute* rest. When the patient can earn his living with the joint immobilized he should be allowed to walk about while wearing the customary splint. A plaster splint encasing the leg and thigh from ankle to perineum is all that is required in the way of apparatus. Rest in bed or extension is not needed; and for this reason the contact of the condyles with the head of the tibia as in standing, or their impact while walking, is not the factor which keeps up the synovitis. We have seen that it is the ligamenta alaria and mucosa and their folds which are the parts most inflamed, and not the articular surfaces of the bones. Moreover, the patient will not show pain if the bottom of the heel is smartly struck, or if he steps heavily upon his heel while the knee is extended. The rest employed as treatment need apply only to flexion and rotation, for it is clearly these motions that stretch or subject to strain those structures which were injured during the initial traumatism, and which should now be at rest.

If properly applied, the plaster splint may be worn for three or four weeks: it is then removed and the joint examined, and, if necessary, the old cast may be reapplied or a new one substituted. It is idle to temporize with these cases of traumatic synovitis of the knee; they must be immobilized so long as there is any excess of fluid in the joint or a continuing point of distinct tenderness about the ligaments; to discontinue immobilization too soon commonly results in a fresh recurrence of symptoms, or at best a protracted course of those already present.

The reason for putting up the leg in a position of full extension is obvious; besides removing strain from the structures about the front of the joint, it allows the bodily weight to be supported upon a column as nearly upright as possible, and prevents jamming of the patella against the confining splint. It is unwise to leave a fenestrum in the splint to allow occasional examination, because the pressure is then unequally distributed over the joint. It will also interfere with resolution and, at best, allow but unsatisfactory methods of examination.

If the patient be seen within the first twenty-four hours, massage may be employed gently over the joint itself, but more vigorously to the thigh above to promote and clear the way for absorption of the effusion. It is also decidedly grateful to the patient. During the stage of active inflammation there must be rest; later, when the active symptoms are subsiding or when of more than six weeks' duration, with effusion still present in a flabby capsule, massage without motion of the joint hastens absorption. It is at this stage that tight strapping and counterirritation are of real service, but they must be continued for some time —a week at least. As for rest in bed, wet dressings, cold applications, etc., during the first few hours after injury, they are of course demanded if the pain, redness and swelling be severe, but such cases are usually accompanied by more serious lesions than the sprains or contusions resulting in simple synovitis. Aspiration is required only in rare cases of excessive distention and tenderness, and should be done aseptically and be followed by firm strapping and bandaging.

There seems to be no royal road to recovery, but, provided the case be uncomplicated, there is a sure road and that road is rest.

THE THERAPEUTICS OF CUTANEOUS DISEASES.

BY ALBERT E. CARRIER, M.D.,

OF DETROIT, MICH.;

PROFESSOR OF DERMATOLOGY AND CLINICAL MEDICINE IN THE DETROIT COLLEGE OF MEDICINE.

I believe that affections of the skin are much overtreated, and that many of them would recover more quickly if a close attention were paid to hygiene, diet, and the patient's habits, without medicines, the application or administration of which, without attention to these points, often works disaster. The manufacturer is daily putting out preparations that, according to the easily-acquired testimonials, are cures for the various dermatoses. The makers of patent medicines preach daily through the public press that they have found a certain cure for all skin diseases. The preparation is usually a lotion or an ointment. This has educated the laity up to the idea that skin diseases are purely local, while the legitimate pharmaceutical preparations for local

medication have had a similar influence upon the medical profession.

The diseased skin cannot be studied as a structure independent of the other organs of the body any more than you can study pathological conditions of the heart, brain, or kidney, without taking into account the inter-relations of the different organs to each other; each is only a part of the whole and each is influenced for good or for ill by the condition of the others. Drug administration or application plays an important part in the treatment of general diseases and medication is just as important in dermatological affections. We should be optimistic regarding the results to be obtained from the use of medicines, having an abiding faith in the drugs that we use, but let that faith be based on the actual knowledge of the action of the drug we are using, and not on mere hearsay, and then, the actual condition being understood, the therapy will be correct.

Here I want to call attention to a familiar fact, but one that is often overlooked, and that is the idiosyncrasy existing in certain individuals whereby the ingestion or application of drugs is followed by a decided effect upon the cutaneous structures which is unusual and may be called an untoward effect. These skin manifestations do not seem to be dependent upon the amount of the drug used. A few drugs that are in common use are in some individuals followed by eruptions of the skin. Quinine is one of the most frequently prescribed drugs in the Materia Medica; a single dose of one-eighth of a grain of this drug in an adult has been followed by an erythema attended by a severe pruritus, lasting for several days and finally ending in desquamation. J. C. White and Stellwagen mention cases in which the single application of a hair-wash which contained quinine was followed by an erythematous rash ending in desquamation. Arsenic is a remedy of very frequent use by the general practitioner in the treatment of cutaneous diseases; this drug is at times followed by papular, vesicular, erythematous, or bullous eruptions, by a pigmentation, or a hyperkeratosis of the palms and soles. An eruption of zoster occurring during the administration of arsenic is very likely due to the drug. Arnica, so commonly used by the laity, is frequently followed by an erythematous or pustular eruption. Chloral, iodine, mercury, copaiba, opium, tar, etc., are at times followed by severe inflammatory conditions of the skin. These effects are always to be borne in mind when treating cutaneous disorders or we may fall into the error of supposing them manifestations of the disease we are treating. A patient with this idiosyncrasy regarding quinine or belladonna and suffering from some cutaneous disease with erythematous manifestations would be improperly treated if these drugs were used. I think that it is not an uncommon occurrence to have syphilitics who are suffering from a drug eruption the result of previous medication come to us for treatment. A continuance of the same line of treatment in these cases would lead to disaster. These untoward effects of ingested drugs illustrate the intimate relation that exists between the digestive tract and the skin.

Because diseases of the skin appeal so strongly to vision and we are able to see the various changes that the different pathological processes undergo, we are apt to lose sight of the fact that the skin is a two-sided organ, that we are observing the changes that are occurring on one side only, and that the other side is the one that will very often deserve the most attention if we are to manage the disease successfully. Anatomically, we may study the skin as a separate structure, but when we come to consider its physiology we find that it is most intimately connected with the entire system, and through the medium of its rich vascular and nervous supply it must respond to pathological conditions of internal organs, and, when itself the seat of a pathological process occupying any considerable portion of its surface, it must also affect internal organs.

Physicians devoting their time to dermatological practice are often asked questions like the following: What shall I do for an eczema of the legs? or, What will cure acne? or, What is the best medicine to use for psoriasis? Such questions are evidences that the inquirer has failed to recognize the fact that the skin has two sides and has confined his investigations to the outside only; or, in other words, he has regarded the process as purely local and the name as always referring to the same condition. Now, there is an eczema and there are other eczemas; there is an acne and there are other acnes; no two cases are alike, nor is a cutaneous affection the same during its whole course. An eczema may be acute, or it may be subacute, or it may be chronic; it is an eczema always, but not the same eczema, and the different varieties require a different medication. Skin diseases are not simply local affections and there are times when, to treat them understandingly, it may be necessary to call in the aid of the thermometer, or the stethoscope, or a urinary analysis.

It is a little strange that, given an organ in which it is so easy to study pathological conditions, where we have the aid of vision, denied us when studying these same conditions in internal organs, diseases of the skin are so little understood. It is an old saying that "familiarity breeds contempt" and I presume that seeing is the familiarity in the case of cutaneous disorders. Many diseases of the skin have their origin in external irritants, during their whole course are purely local in character (this is to be expected on account of the skin occupying a position so exposed to injuries, temperature changes, attacks of parasites, etc.), and are usually speedily cured on removal of the irritant; at other times, however, the simple dermatitis may end in an eczema, requiring in addition to a different local treatment constitutional medication, and the

knowing of when this change occurs is the important factor.

There is no specific medication for diseases of the skin if we except the syphilides, and even syphilitics are at times much benefited by omitting all specific medication and directing the treatment as though the patients were suffering from some disease other than lues. Cutaneous affections should be cured as speedily as possible. We have gotten over the idea that eruptions of the skin must be handled with care for fear of causing them to disappear too rapidly and transferring the process to some internal organ. The quicker we get rid of skin lesions the better, for, as already stated, local irritations long continued may result in disturbance of some internal organ, and eruptions of the skin are local irritants just the same when occurring as a result and in the course of a special disease. Bearing in mind the tissue of the skin and its structure, its diseases are to be treated just the same as those of any other organ with the same pathological condition.

Inflammations of the skin are acute, subacute, or chronic. Redness, heat, swelling, and pain are the same whether occurring in an acute dermatitis or an acute eczema, and it is the condition that calls for treatment; the acute process calls for one medication, the subacute for another, and the chronic for still another, no matter in what disease the conditions may occur, and this is especially true of local therapy. Because the lesions in many cutaneous disorders are very small, though the eruption may have a large distribution, we are apt to lose sight of the fact that it is the process occurring in the individual lesion that we are to comprehend. How does it develop? What is its course? How is it resolved? A knowledge of these conditions enables us to direct a therapy which at one stage may be necessary to aid the process, while at another it must be combated.

Dermatological affections may be divided into three classes:

1. Those that are self-limited, usually running a definite course, attended by mild or severe subjective symptoms, and ending in recovery. Cases in this class are usually acute and require little in the way of treatment other than relief of the distressing symptoms. Active treatment in these cases may do much harm, and it is diseases of this class that are so often overtreated.

2. Those that are benign in character but incurable and those that are fatal in spite of all medication; the malignant growths, if operable, will come under the care of the surgeon; if otherwise, our efforts will be directed to the relief of distressing symptoms.

3. All other cutaneous diseases will come under this class, and it is here that we find our opportunity to cure. It is in this division that occur cases calling for active, and thorough medication with a prospect of good results; it is here that occur cases that we are able to control and these cut short the disease, which may last indefinitely if not treated; and it is here, too, that cases are apt to become inveterate from inappropriate treatment.

Naturally enough, when undertaking the care of a skin disease, the question will arise as to whether it will require internal medication, or whether local treatment will be all that is necessary, or whether a combination of both methods will give best results. From the exposed situation of the skin it is liable to injuries from occupations, from the ravages of parasites, from temperature changes, etc., resulting in a purely local affection, and in these cases removal of the irritant and a local therapy will be all that is required if the patient is up to the normal standard of health; but scabies, ringworm, or a simple dermatitis in children with defective assimilation or elimination may refuse to yield to the ordinary medication until these defects are removed.

In caring for cutaneous diseases of infancy and early childhood, the first inquiries should be regarding the ordinary every-day care of the skin. I am positive that many of the cases of eczema at this time of life are the result of the lack of proper care. A baby ushered into the world from the most bland surroundings is placed in the care of some one to be washed and dressed, a process that usually results in a highly-colored, rosy integument, which is exhibited as an evidence of perfect health, and when later on, and probably as a result of this cleaning process, the skin rebels and becomes diseased, the cause is overlooked and the internal organs are interrogated for the source of irritation. The epidermis of a young child is easily removed, and the rubbing to promote a healthy color deprives the skin of its natural protection. Washing for cleanliness is essential to the health of the skin, but anything beyond that is harmful. The skin of an infant, or young child must be treated with profound respect. In children a little beyond the age of infancy overeating is a fruitful source of cutaneous diseases; often this overfeeding is not attended with symptoms that call attention to the gastric apparatus, but in all the skin affections of early childhood the amount and kind of food that the patient is taking must be looked after and regulated by the medical attendant, and he should also specify the hours of feeding. Attention to the regulation of diet and hygiene will often overcome a disease that has resisted a thorough course of medication, both internal and external.

If attention to diet and hygiene be necessary in children, it is equally necessary in adults. It is a matter of surprise in questioning patients to find the amount and kind of stuff the average individual puts into the stomach daily. Young women will tell of eating a pound of candy every day and exhibit surprise when told that it must be stopped; add to this several glasses of soda water, and late suppers, etc., and it is little wonder that a skin disease results, even if there be no gastric symptoms severe enough to attract attention. Sweets are bad for some cutaneous affections, and hot soups and late suppers are

worse. A correction of habits is necessary if we are to treat successfully skin diseases. A matter that impresses me more each day is that it is necessary that we see our patients often. Pathological processes of the skin change their character often and a therapy for to-day may be improper to-morrow. It is hard to convince patients that they are sick when they are able to attend to their ordinary vocations, but better results will follow if we are able to do it.

An increasing experience in the treatment of cutaneous diseases leads me to the conclusion that among a large proportion of general practitioners the opinion prevails that there is a specific medication for skin diseases, for I find that generally the cases that are referred to me have been treated by arsenic, mercury, or iodide of potash. All these are valuable drugs in properly-selected cases, but capable of doing immense harm when used indiscriminately. It would be far better to leave them entirely alone until all other resources have been exhausted. A correct diagnosis is essential in treating skin diseases. I am positive that mercury and the iodides are often given when an incorrect diagnosis has been made simply from the skin lesion, which in a number of diseases may look like a syphilide.

Regarding general treatment I have little to say. The practitioner is familiar with all conditions of ill health and perfectly competent to direct a therapy for their removal. I want to call attention to a few of the drugs that are in such common use in the treatment of cutaneous diseases. If reliable statistics could be obtained of cutaneous diseases treated by arsenic alone, and benefited, or cured, and of those in which its use had been followed by no benefit or untoward effects, we would find that the latter would far outnumber the former. I am positive that more harm than good follows the use of arsenic in skin diseases. There are only a few cutaneous disorders in which the drug may be used with a fair prospect of doing good, and even in these not all the conditions are suitable for its administration. It had better not be used at all than used indiscriminately. The action of arsenic seems to be upon the epidermal structures; whether by its influence upon the nervous system or as a direct irritant is a question, but from the known benefit that follows its use in neurotic cases of eczema, pemphigus, etc., I am inclined to the opinion that the former is the correct theory. Arsenic is never to be given when there is an acute inflammation of the skin. In chronic affections characterized by epidermal exfoliation it finds its sphere of usefulness. In psoriasis, squamous eczema, lichen planus, pemphigus, it may be used with a reasonable expectation of benefit resulting, but even in these diseases it is better to try other remedies first, and then, if arsenic is decided upon, it must be used thoroughly, as the action of the drug is slow and it should be given for a long time in order to accomplish a cure. Failures from its use may often be attributed to an impure preparation, a fact that should be remembered.

The alkalies are an exceedingly valuable class of remedies in cutaneous disorders and are indicated whenever there is a congestion of active character. In acute eczema, in the acute stage of psoriasis, in the various erythemata, and in skin diseases occurring in gouty or rheumatic individuals, this class of remedies will be found of great value.

Antimony deserves more consideration as a remedy in cutaneous disorders than it is getting. I know of no remedy that gives as good results in the dermatoses occurring in the robust individual with the florid complexion, the hearty eater, whose diet is largely meat, as antimony. It relieves the congested skin and assists in eliminating the waste products through the alimentary canal and kidneys. Try antimony instead of arsenic.

Mercury, of course, finds its greatest value in the syphilides, but it is also very useful in those affections that are characterized by induration of the tissues, such as we find in old cases of eczema. A short course of mercury will act very kindly in causing absorption of the exudate. In small doses in the eczemas of children, and especially those that are pustular in character, in an active psoriasis, particularly if occurring in those of full habit and florid complexion, in the cutaneous disorders of the gouty and wherever there is defective elimination, in the various erythemata, in rosacea, etc., it is of great value.

The salicylates find a sphere of action in cutaneous disorders that are characterized by congestions and in those of a rheumatic or gouty character. In those cases of urticaria that are not dependent upon some disturbance of the digestive apparatus it seems almost a specific. Ichthyol, one of the newer remedies, is of value in the various vasomotor disturbances and in cases of acne occurring in the plethoric, also in urticaria and in rosacea.

Calcium sulphide in some cases seems to interfere with pus formation, while in others it seems to hasten the process in pustular lesions that are slow in resolving, and is useful in many of the acnes, furunculosis, etc. I have had better results from small doses often repeated than from the large doses. It is necessary that the drug be pure and it should be given in gelatin-coated pill.

The iodides are useful in assisting the elimination of waste products, such as are found in old cases of psoriasis, in indurated acne, etc. They are also valuable in cases of furunculosis, when there are many lesions and distributed pretty well over the body, in the slow-developing lesions of tuberculosis of the skin that used to be known as evidences of scrofula. Its action in the later manifestations of syphilis need only to be mentioned. Untoward effects sometimes follow its use and they must be watched for and avoided. The roborants, such as cod-liver oil, the various preparations of malt, etc., will occur to all.

The newer preparations in the management of cutaneous disorders are most of them being used

tentatively; we are not positive that they are better than the drugs that we are perfectly familiar with, and they had better be avoided until their usefulness has been positively demonstrated. With the careful use of the drugs that I have mentioned most of the cases of skin disease that come under the care of the general practitioner can be successfully managed in so far as internal medication may be necessary.

In the field of local therapy in skin diseases lies the opportunity of brilliant cures, or miserable failures, depending upon whether we are or are not familiar with (1) the pathological condition existing and the efforts that Nature is making to overcome this, and (2) an accurate knowledge of the effects of medicines when applied to healthy or to diseased skin. A knowledge of these two requisites enables us to select a remedy that will combat the pathological process and at the same time aid Nature in her efforts at repair.

Time will not permit me to call attention to the various local applications that are found useful in the management of skin diseases; I will simply make a few suggestions concerning the principles of local therapy.

1. The removal of all sources of irritation to the skin. Inquiries may show that the occupation of the patient, the methods and material used for the purpose of keeping the skin clean, or the clothing that is worn may be the means of lighting up a skin affection, or of continuing it when occurring from some other cause.

2. Absolute cleanliness. This means rendering the skin aseptic. The removal of all disease products from skin lesions lessens the liability to secondary germ infection, while their decomposition furnishes an added irritant. A process of cleaning should be accomplished with the blandest of material, and the utmost gentleness to avoid irritation.

3. The relief of distressing subjective symptoms of pruritus, smarting, or pain. An infant suffering from an eczema will do more harm in a minute by its efforts to relieve the itching by scratching than we may be able to overcome by a week of appropriate treatment.

4. The selection of the proper vehicle for the incorporation of the drug we are to use and a proper preparation of the application. Ointments and powders require the exercise of brain and muscle, if they are properly prepared, and a limited experience with pharmacists will convince any one that there is a great difference among them regarding the way in which these applications should be prepared. Success or failure in local treatment will largely depend upon properly-compounded applications, and the writing of a prescription does not end our duty to the patient.

5. The proper application of the remedy. A fact that should always be remembered is that the intermittent application of even soothing remedies will have an irritant action upon the lesions, and hence the ordering of an ointment of oxide of zinc for an eczema, in which it is indicated to be applied morning and night, would be improper, for, if the remedy is indicated, the application must be in constant apposition to the part as long as the indication lasts. I think that this is a matter of much importance.

With attention to the few suggestions made, the general practitioner is just as competent to manage cutaneous affections as the specialist, barring, of course, the greater experience the latter has from his larger clientèle.

100 Miami Avenue.

MEDICAL PROGRESS.

THERAPEUTICS.

Treatment of Hemorrhoids by Electricity.—The advantages of treatment in these affections by electrical currents of high frequency and tension are set forth by R. Pisani (Annali di Elet. Med. e Ter. Fis., Feb., 1902). After reviewing the experiences of other clinicians, the author gives the details of a case so treated in his personal practice, the favorable results coinciding with the apparently invariable success reported from the use of this method. The electrical current was applied daily to the diseased site for from five to eight minutes, the intensity of the current being from two to four amperes. The patient experienced no discomfort from the passage of the current, a sensation of slight warmth at the anal orifice being the only noticeable effect. Abolition of spasm of the sphincter was obtained in a few days, permitting the easy passage of the electrode; sphincteralgia diminished markedly after the first applications and disappeared entirely at the end of ten days; internal and external hemorrhoids, which were numerous and voluminous, gradually became less painful, and they, too, were entirely obliterated after ten treatments. The patient's general health improved steadily during the local treatment, and there has been no recurrence of trouble during the five months he has been under observation.

Atropine in the Treatment of Ileus.—It has been observed when pursuing this method of combating certain forms of intestinal obstruction that small and continued doses given for several days almost invariably produced toxic symptoms, whereas the majority of patients who had given large doses rarely showed any such effects. An explanation of this phenomenon is proposed by A. Weber (Deut. med. Woch., Feb. 6, 1902). Atropine is known to be antagonistic to morphine and, as almost all cases of ileus are treated in the early stages with opiates, the small hypodermic doses of atropine are readily neutralized and have no effect on the intestinal spasm. A larger dose (0.005 gm.) does not call forth toxic symptoms, as only the part which is not neutralized comes into effective action. The author believes that a knowledge of this antagonism affords also a means of controlling the effects of atropine administration. He finds from the experience of his own and other cases that atropine can be used in all forms of ileus, as even in the surgical cases the drug lessens the pain and induces bowel movements after the operation. The intestinal obstruction following laparotomy or herniotomy, unless due to volvulus or incarceration, should be treated with atropine in preference to opium. The fecal accumulations in large scrotal herniæ of old people are often relieved. As for the dose, if the patient be under the influence of opiates, a hypodermic of 0.005 gram ($^1/_{40}$ gr.) can be given and repeated in twelve hours. If very little or no opium

have been given in twenty-four hours, only 0.002 grams (1/100 gr.) should be injected, followed in twelve hours if necessary by the larger dose. If no gas be passed in twenty-four hours after the first administration, laparotomy is indicated.

Frost-Bite and Peroxid of Hydrogen.—Chilblains are a common and troublesome affection the world over, and the many methods of treatment prove that none is absolutely reliable in all cases. J. Courtin (La Sem. Méd., 1902, No. 5) has been using peroxid of hydrogen in treating this condition whether with or without ulcers. He immerses the affected parts for half an hour every day. For small children he employs the pure product reduced to two or three times its volume by the addition of warm boiled water. For children over three years of age and for adults he uses a half-strength solution. If there be ulcers this author adds to the peroxid of hydrogen a saturated solution of borate of soda in order to decrease the acidity of the liquid and the amount of pain which it produces. He states that the results he obtains are prompt and satisfactory.

Treatment of Lobar Pneumonia.—The discovery of the specific cause of pneumonia aroused hopes that in the near future a specific cure might be found. The serum treatment has been advocated by many as fulfilling this indication, but experience has shown that it has little if any effect. Pneumonia, perhaps more than any other disease, must be treated according to the particular symptoms which arise, says C. E. Nammack (N. Y. Med. Jour., Feb. 15, 1902), and hence the physician must be able to study and appreciate the individual case. So far as drugs are concerned he pins his faith in nearly all cases upon four: Strychnine, whisky, nitroglycerin and oxygen. The strychnine and nitroglycerin are given in moderate and frequently-repeated doses combined with a dram of the wine of pepsin. Whisky is well borne and can usually be given in large doses. It has the disadvantage of causing relaxation of the peripheral vessels, but this action can be overcome by the use of strychnine. The benefit from oxygen may be problematical, but it certainly gives the patient relief and frequently renewed courage. Creosote has been highly extolled by some observers and, although undoubtedly of value in many cases, its specific action is doubted. The rectal and subcutaneous injections of a saline solution are more rational and are especially indicated when the kidneys and bowels are deficient in action. Before the subcutaneous or intravenous injection of fluids, a preliminary venesection should always be done to avoid any considerable increase in the body fluids. A temperature below 104° F. seldom needs any treatment, but above that point cold or tepid baths act well as antipyretics and as cardiac stimulants by increasing the tone of the peripheral vessels. The chief cause of death is degeneration of the myocardium, due to toxemia and the amount of lung involved.

Practical Pharmacy.—The lack of instruction in pharmacy not only hampers the physician in the art of prescribing, but frequently leads him into making mistakes which may seriously change the action of the drugs. E. T. Hargrave (N. Y. Med. Jour., Feb. 22, 1902) has suggested several rather frequent combinations which the pharmacist is called upon to make and in which the desired results cannot be obtained. Quinine is sometimes made soluble for administration by the addition of dilute sulphuric acid and then glycyrrhiza is added to disguise the taste. Unfortunately, the sweet principle of licorice is precipitated by an acid and the mixture is made much more bitter. An excellent way of administering chloral is by adding syrup acaciæ, U. S. P., ℥ss., and tinct. cardamom. comp., ♏. x., to each dose. An emulsion of turpentine for internal use may be made as follows: Place the finely-powdered acacia in a perfectly dry bottle in the proportion of twenty grains to the ounce of oil; add the entire quantity of oil and shake vigorously. Then add half an ounce of water and shake till globules of oil cease to be seen on the sides of the bottle. Add gradually the remaining water, shaking well after each addition.

Treatment of Erysipelas.—The results following the application of an old remedy, continuous warmth, to erysipelatous areas have been found excellent by M. Jerusalem (Klin. therap. Woch., Feb. 16, 1902). The infiltration and reddening begin to disappear in from one to three days, and, though the temperature may persist, the pain is relieved rapidly. Abscesses are said to complicate erysipelas of the extremities in 64 per cent. of the cases; however, not one single instance was observed in 25 cases treated with heat. The best way to apply this heat is by means of a thermophor. The author's experience with antistreptococcic serum has been very disappointing.

Therapy of Auto-intoxication.—Intestinal lavage has during the last few years been strongly urged, especially by Boas, as only second in importance to purgation in the treatment of this condition. Many observers even affirm that no permanent value can be obtained by the administration of antiseptic drugs alone. While recognizing the benefits to be derived from colon irrigations, B. Robinson (Med. Rec., Feb. 15, 1902) believes that too little attention is paid to certain intestinal antiseptics which assist in preventing fermentative changes and still are not strong enough to derange the normal digestive functions. The argument which has been used against such drugs has been that whatever inhibitory action may be exercised by them over the development of certain bacteria, this inhibition is exercised even more strongly over the healthful action of the viscera affected. Three drugs have proven very satisfactory in the hands of the author in meeting the indications in such cases; first, creosote in small doses combined with the elixir of pepsin; second, wood charcoal; and third, the subnitrate of bismuth. In certain cases, dilute phosphoric acid has proven more valuable, especially when the nerve tone is lowered. The electric baths, abdominal massage and static electricity are useful in many cases, especially when combined with purgation and intestinal lavage. The malnutrition which results in such patients leads frequently to gastroptosis, enteroptosis, displaced liver, kidneys, etc., which often come under the surgeon's knife. The author suggests that if these cases could be followed for a few years, the percentage of cures after operation would be extremely small and he, therefore, seldom recommends surgical interference.

Treatment of Eclampsia by the Method of Stroganoff.—Stroganoff's method of treatment is designed to accomplish the following results: (1) Prevention of the convulsions by lessening the irritability of the nervous system and by removing all external sources of irritation, especially those connected with the birth canal. (2) Strengthening of the vital processes by careful supervision of the cardiac and pulmonary circulations, by securing as large a quantity of oxygen as possible, and by prompt delivery, if, with these measures and a proper diet, the convulsions do not cease. The treatment is in brief as follows: The administration of oxygen during the convulsions; the use of morphine and chloral to control the convulsions; the free use of cardiac stimulants when the heart weakens; a milk diet; avoidance of all methods of treatment which tend to depress the patient. The use of normal salt solution is advised as the most satisfactory method of stimulation, although brandy and sulphuric ether may be used for sudden emergencies.

Stroganoff believes that the single dose of morphine should never exceed ¼ grain. He believes that the ordinary use of hot-water baths and of hot air depresses the already overburdened heart and increases still further the nervous irritability and thus favors the recurrence of the convulsions. A warm bath to cleanse the skin has no harmful effects and is soothing. Within the last few months nine cases of eclampsia have been treated in Boston hospitals in accordance with the principles of Stroganoff, and in the main, according to F. S. NEWELL (Boston Med. & Surg. Jour., Feb. 20, 1902) the results proved satisfactory, postpartum cases in particular yielding readily to the sedative treatment. In the remarkable series of cases reported by Stroganoff, 58 were cases which came under his own observation and the hitherto unheard of result of no mortality was obtained.

Treatment of Tetanus by Baccelli's Method.—The question of rheumatism and other etiological factors in the induction of tetanus in which infection cannot be traced to an external wound is discussed by E. CIOFFI (La Riforma Medica, Jan. 20, 21, and 22, 1902). The author believes that rheumatic tetanus cannot be considered a separate pathological entity, but that all cases of tetanus are due to infection with the bacilli of Nicolaier, and that exposure to cold, dampness, etc., but is a predisposing cause. In individuals in whom no external wound is visible, infection is to be attributed to the presence of the specific bacilli in the mouth, nose, bronchi or intestines. Statistics of treatment by tetanus antitoxin are quoted, showing a mortality of from 50 to 80 per cent.; contrasted to this, Baccelli's method of treatment by hypodermic injection of carbolic acid has given brilliant results, the mortality being estimated at from 12 to 30 per cent. The dose should never be less than one centigram to the kilogram of body weight; 3 grams have been administered daily without ill-effect.

PHYSIOLOGY.

Relation of Lipase to Fat Metabolism.—Not until clear ideas on the subjects of fat absorption and fat metabolism are obtained will one be able to make any definite progress in the study of the pathological problems connected with fatty degeneration and fat accumulation in the body. Substantial contributions are being made in this field. A. S. LOEVENHART (Amer. Jour. of Physiology, Feb. 1, 1902), prompted by the recent demonstration of the reversible action of lipase, ordinarily known as the fat-splitting ferment of the pancreas, which reversible action is shown in its ability to break up as well as to form fats, according to circumstances, has conducted a research in order to throw light on the history of fat in the organism. Although under certain circumstances, lipase may act as a lipolytic or fat-splitting ferment, and under other circumstances as a lipogenetic or fat-forming ferment, in either case its action is incomplete. In the intestine it splits fats into fatty acids and glycerin. These are absorbed by the epithelial cells in which these occur, as the result of the farther action of lipase, a partial synthesis of these elements, with the formation of fat. This synthesis is due to the effort on the part of the lipase to establish equilibrium between the fatty acids and the glycerin. But the latter is being constantly diffused from the attached border of the cells. The fat remaining in the cells would be immediately broken up by the lipase unless there were an immediate absorption of fatty acids and glycerin from the lumen of the intestine. Evidently the importance of the fat in the cells is not great, for none of it passes as such into the lacteals. In the thoracic duct the fatty acids and glycerin are found largely synthesized. Munk believes that this synthesis occurs in the lymphatic glands. To determine to what extent this is true, Loevenhart studied the action of extract of the lymphatic glands and lymph, and found that they have considerable lypolytic effect. This result simply demonstrated the presence of lipase in the lymphatic glands and lymph, without showing any synthetic power possessed by the same. To throw light on this subject, Loevenhart studied other tissues and found lipase present not only in the pancreas and lymph-glands and lymph, but also in the kidney, to a large extent in the liver, in the submaxillary gland, in the intestinal and gastric mucosa, the mammary gland, blood, brain, spleen, somatic and heart muscle, and to a considerable extent in adipose tissue. Its presence in abundance in the last is accounted for by the fact that during inanition the body can absorb its own fat, the lipase in the adipose tissue splitting it up in order to allow it to be "translocated" to the blood for instant consumption. This universal presence of lipase in the tissues seems therefore to be connected with the synthesis of fat, for its quantity varies according to the amount of fat found in the individual tissues. Lipogenesis is analogous to glycogenesis. The adipose tissue bears the same relation to the storing up of fat as the liver does to the storing up of glycogen. Although the liver contains more lipase than any other tissue, it normally contains very little fat, the normal structure of the liver being unfavorable to fat accumulation. Under pathological conditions, however, fat is stored up with ease and rapidity. The fatty degeneration incident to phosphorus-poisoning is not due to lipase, for the latter is not found in excess in cases of this condition experimentally induced.

Sensitiveness of the Skin to Heat.—In a contribution to the "Knowledge of the Topography of Heart Areas," E. VRESS (Pflüger's Archiv, Jan. 22, 1902) gives some valuable information. He divided the entire cutaneous surface into small quadrilateral areas, and by means of the thermesthesiometer he determined the degree of heat that in each area arouses the sensation of heat and the degree that arouses the sensation of pain. He tabulates these results and gives figures representing by means of shaded areas the varying sensibility of the skin. The sources of error in such an inquiry are to be attributed to the effects of adaptation, presence or absence of moisture, after-sensibility, hyperemia, fluctuations in the zero-point, and the presence and character of accompanying sensations. He finds that the left side of the body is more sensitive to heat than the right, the median surface of the trunk less than the lateral, and the lower limbs more than the trunk. In the last the sensibility to heat diminishes toward the distal parts, but not by regular stage. In fact some distal points on the extremities are more sensitive to heat than certain proximal points. The lateral surfaces of the extremities are less sensitive than the median. To what are these variations in sensibility due? Keeping in mind the causes of error mentioned, they are due to either the variations of innervation, the varying quality of the skin, or possibly both. The degree to which a portion of the skin is normally accustomed to high temperatures has a marked effect in diminishing its sensitiveness to heat. Thinness of the skin is, as a rule, associated with greater sensibility. The effects of habituation are supposed to cause some transformation in the structure of the skin. Veress found the lumbar region to be the most sensitive region and the soles of the feet to be the least sensitive; next the postauricular region of the scalp, and next the palmar surface of the fingers. Eliminating the soles of the feet on account of the effect of callosities in diminishing sensibility, Veress concludes that the portion of the body least sensitive to heat is the

postauricular region of the scalp. It is impossible to determine the purely ideal sensibility of the skin to heat from the standpoint of innervation, for it is impossible wholly to eliminate the effects of the condition of the epidermis and the effects of habituation and practice.

Subcutaneous Alimentation and Formation of Bile.—To determine the value of subcutaneous alimentation A. G. Barbèra (Bull. delle Scienze Med., 1902, Series viii, vol. i.) conducted a series of experiments upon a dog, the substances injected being somatose, glucose, olive oil, and distilled water, the elimination of bile and excretion of urea being noted in each case. There was no increase in any of these substances after injection of distilled water, 100 c.c., glucose, 10-per-cent. solution sterilized olive oil in moderate quantity, or somatose, 5-to-7-per cent. solution; neither was there local reaction. Elimination of bile and excretion of urea were increased after injection of glucose, 20-per-cent. solution, non-sterilized olive oil in large quantity, and somatose, 10-per-cent. solution; these injections gave rise to some local reaction. It is believed that the increase in excretion of urea, etc., in the latter series of experiments was due not to absorption of the substances injected, but rather to reactive processes induced by them through non-sterilization, concentration or excessive amount, causing destruction of the proteids of the body in more than the usual quantity, and the products of their decomposition passing through the liver, where they are chiefly converted into urea, effected an increase in the functions of that organ and increased production of bile. The hypotheses advanced in a previous paper are reiterated, the results of these experiments being considered as confirmatory to a degree of the principles they embraced, *i. e.*, that the increase in the quantity of bile after meals is due to the presence in the liver, and not in the intestines, of nutritive principles derived from the alimentary canal; and the production of bile is determined by the presence in the liver of certain substances derived directly from the organism itself, as is seen in intra-uterine life, in inanition and during the period of lethargy in hibernating animals, the production of bile being proportionate to the quantity of such substances and nutritive principles found in the liver. The author deduces from the experiments cited, that subcutaneous injections of nutritive substances are much less valuable than is their administration by rectum.

NEUROLOGY AND PSYCHIATRY.

Intracranial Tumor.—The diagnosis of such a condition in a man of thirty-seven years was made by J. Stewart (Montreal Med. Jour., Jan., 1902) because of constant severe headache, vertigo, bilateral optic neuritis, exaggerated knee-jerks and ankle-clonus. It was localized on the left side at the lower part of the ascending frontal convolution, because of spasms and weakness of the muscles of the lower part of the right side of the face, paresis of right side of tongue, and slight paresis and disturbed sensations in the right arm and hand. It was thought to be subcortical, because of absence of general aphasia and the presence of progressive dysarthria. It was near the cortex, because of the muscular spasms and because a unilateral lesion to induce dysarthria must be sufficiently near the cortex to include not only the speech tracts which pass down the same side, but also those that cross over in the corpus callosum and pass down the opposite side of the brain. Antisyphilitic treatment proved ineffective, and the good nutrition of the patient and absence of tuberculosis elsewhere made tuberculosis improbable, so a glioma was suspected and an operation was performed. The tumor was found to be an encapsuled, firm, whitish glioma, measuring one inch by one-half to three-quarters, and was removed. The patient's articulation after operation became somewhat worse, but on the eighth day began to improve, so that at about the third week he was able to articulate words of two or more syllables. At the end of four weeks, speaking slowly, his articulation was nearly normal. The paralysis disappeared and the patient was discharged cured.

Pelvic Lesions and Mental Disturbances.—Among lunatics there are more single than married men and more married than single women, writes A. Thobbs (Amer. Jour. Obstetrics, Feb., 1902), and this may be accounted for because single men lead more irregular lives than do married men, so favoring subsequent mental collapse, and married women, owing to injury and disease entailed by maternity, are more subject to mental degeneration than are those who are free from pelvic troubles. At the Asylum for the Insane, London, a pelvic examination in one thousand females disclosed disease or abnormality in 25 per cent. Medical treatment was found difficult to carry out and non-productive of result, so operation became the routine practice. The lesions were tabulated under six headings, viz.: Ovarian disease, abnormal displaced uteri, tumors, cervical lesions, diseases of the uterine body and endometrium, and injuries to the perineal body. Eighty-four cases of acute mania were operated upon with mental recovery in fifty-one; one hundred and five cases of chronic mania with recovery in nineteen; five cases of epileptic mania without any recoveries; fifteen cases of puerperal mania, with recovery in seven; four cases of folie circulaire with one recovery; one case of psychocoma with recovery; twenty-five cases of acute melancholia with recovery in thirteen; thirteen cases of chronic melancholia with recovery in six; two cases of puerperal mania with recovery. Some of the cases that failed of cure showed more or less improvement in the mental condition. The mental results of operations for hernia in 39 patients of both sexes were almost nil.

Treatment of Paralytic Attacks.—As a guide for the treatment, the paramount fact must be advanced that the patient generally succumbs to the effects and complications which finally occur, and it is against these that therapeutic or rather prophylactic measures must be directed. A. Pick (Phil. Med. Jour., Feb. 8, 1902) believes that the interruption of the attack should be considered first, as it is often influenced by the irritation of a filled bladder or rectum or often of an unobserved furuncle, and finally, especially in children, by some slight febrile affection. He does not believe in any specific against the attack itself and considers unfavorably the injections of ergotin often recommended. In addition to the local measures directed against decubitus, careful attention must be given to the disinfection of the accessible parts of the alimentary canal. The proper cleansing of mouth and nose may obviate pneumonia and high enemata of water or boric-acid solution will prevent auto-intoxication from the intestine, which has often been held responsible for the attacks themselves. To overcome the danger of deglutition pneumonia the nourishment should be liquid, but the power of swallowing should first be tested. When this act is interfered with, rectal alimentation is preferable to the use of the pharyngeal sound. The enemata should be small and bland. To combat the increased elimination of water during the first few days, simple saline enemata should be given every hour.

The X-ray in the Diagnosis of Lesions of the Brain.—The second case on record in which a brain tumor was localized during life by means of the X-ray is reported by C. K. Mills and G. E. Pfahler (Phil. Med. Jour., Feb. 8, 1902). A clinical diagnosis was

made from the general symptoms and from the combination of motor paralysis with impairment of cutaneous sensation, astereognosis and hemianopsia, of a dense tumor of large size in the parietal region, chiefly subcortical, possibly invading the motor region and extending to or compressing the posterior limb of the internal capsule and the optic radiations near the basal ganglia. The negative obtained by the X-ray showed a large shadow lying between the coronal suture and the posterior meningeal artery. Experiments made on cadavers, with hardened tumors placed in artificial cavities of normal brains, likewise showed appropriate shadows. The authors conclude from other experiments that in addition to the detection of tumors proper, other abnormalities and deficiencies in brain substance can also be detected, which will probably be of value in the diagnosis of cysts, softening and hemorrhages. It is necessary, however, to exercise great care in differentiating the abnormal shadows from those obtained from normal parts of the brain.

Cerebral Bulbar Palsy.—Paralysis of the tongue from disease of a single cerebral hemisphere, though always associated with hemiplegia, is not at all uncommon, but still is difficult to explain, as the tongue is an organ the movements of which are made symmetrically, and which has, as would be expected, a bilateral representation in the cortex. An interesting case of bulbar paralysis is reported by C. L. Dana (Phil. Med. Jour., Feb. 8, 1902) in a man sixty-seven years of age, who was admitted to the hospital with the history of an attack of left-sided hemiplegia. The incomplete paralysis of the left arm, leg, and lower side of the face was accompanied by a distinct and complete paralysis of the tongue and by a partial paralysis of the lips. The patient died three weeks after the attack, the hemiplegia having improved, but no change having been noted in the condition of the tongue and lip palsy. Autopsy showed a focus of hemorrhagic encephalitis involving the cortical and subcortical tissue in the lower and posterior end of the posterior central and the adjacent inferior parietal lobule. From a study of his own and other reported cases, the author concludes that the tongue and lip centers are probably more or less identical. One group of centers for the tongue is in relation with the articulatory movements of the lips and another with the movements of mastication. Paralysis of the tongue and to some extent of the lips from a one-sided cortical lesion occurs and may perhaps be explained by the fact that in many individuals the brain becomes accustomed to using only one center in controlling the movements of these parts, causing a paralysis of these when the center is destroyed. When the center on the other side becomes awakened to its capacity, it takes up these movements and the paralysis disappears. This theory may explain also the frequent difficulty in deglutition and articulation, in many cases of hemiplegia due to ordinary cerebral hemorrhage. That a permanent bulbar palsy can be caused by a cortical lesion of one hemisphere is doubtful and if it occur it must be regarded as an anomaly.

MEDICINE.

Acute Syphilitic Nephritis with Extreme Albuminuria.—Although Karvonen collected a series of cases of true acute syphilitic nephritis, the possibility of this condition is not generally recognized. The most skeptical critic, writes E. Hoffman (Berl. klin. Woch., Feb. 10, 1902), must admit that in a certain number of cases acute nephritis has occurred during the early stages of syphilis in previously healthy individuals, and that such nephritis has been cured by mercury. It is not easy to see why syphilis, which from the eruptive period, is a constitutional disease capable of affecting any or all the bodily organs, may not affect the kidneys in the same manner as any other infectious ailment. Hoffmann reports a case of acute syphilitic nephritis occurring in a man of twenty-three, who, however, gave a history of having had scarlet fever when five years of age. Following an infection occurring in June, the patient had an eruption early in August. A few days later the patient noticed that his urine was darker than the normal color and of diminished quantity. Urinalysis early in September showed, according to Esbach's method, 7 per mil. of albumin after dilution of the urine with nine parts of water—*i.e.*, the equivalent of 7 per cent. of albumin. Hyaline casts were present. Salkowski was asked to make a careful quantitative analysis of the urine, and found in two examinations 8.5 and 7 per cent. respectively of albumin by weight. Under treatment with mercurial inunctions the albumin and casts gradually disappeared, together with the ordinary syphilitic manifestations. Justus demands, for the proof of the syphilitic origin of albuminuria, evidence on three points: (1) Healthy kidneys before the beginning of the specific disease; (2) the occurrence of albuminuria must go hand in hand with other manifestations of syphilis, and (3) the albuminuria must respond in an unmistakable way, either by marked improvement or by cure, to treatment by mercury. The last two conditions are thoroughly established in Hoffmann's case, and a careful analysis of the history of the case makes it appear probable that the first condition also existed.

Is There a Fourth Disease?—About a year ago Dr. Dukes declared that he had found a disease which resembled scarlet fever, measles and rubella, but which could be distinguished from them all and hence was known as "the fourth disease." In an attempt to confirm this opinion, C. B. Ker (Practitioner, Feb., 1902) has been watching for cases illustrative of the new disease, but as yet has been unable to satisfy himself of its existence, although his experience is very wide. A number of very valuable hints are given in the course of this article relative to the differential diagnosis of these eruptive diseases. Scarlet fever usually has a very short period of incubation, from three to five days, while measles takes from ten to thirteen days to develop. Scarlatina has an abrupt invasion associated with marked symptoms, a rapid rise of temperature accompanied by headache, vomiting and sore throat, the rash appearing usually within thirty-six hours. Measles has a more insidious invasion, lasting four days as a rule. The symptoms are those of catarrh, sneezing, coryza, running at the eyes, photophobia, and cough. There is no sore throat or vomiting, but a well-marked stomatitis. Koplik spots may usually be seen if the throat be examined in bright daylight. With the eruption the characteristic signs appear. In scarlet fever the bright scarlet, finely-punctate rash is first seen on the sides of the neck and the upper part of the chest. The face is flushed, but the rash as a rule avoids it, merely appearing at the angles of the jaw. The circumoral region stands out, unaffected by flush or rash, as a distinct white ring round the mouth. The conjunctivæ remain clear. In measles the rash covers the whole face, beginning from the roots of the hair and behind the ears. The eyes are suffused and the circumoral region is affected. The rash is composed of raised, velvety papules, coalescing into irregularly-shaped macules, varying in color and being less bright than scarlet fever. Scarlatina presents a bright red appearance of the fauces with perhaps some swelling of the tonsils and a strawberry appearance of the tongue. In measles sore throat is seldom complained of, but the mouth is usually congested and dirty and no strawberry appearance of the tongue is present. Scarlet

fever temperature falls by lysis, that of measles by crisis. There is a branny desquamation in measles, but it can in no way be confused with the characteristic worm-eaten appearance of the peeling in scarlet fever. In rubella the incubation is from ten to twenty-one days and seldom are there any symptoms of invasion. Occasionally a slight sore throat or coryza may precede the eruption. The eruption consists of small discrete spots, larger than the punctate spots of scarlet fever and smaller than the papules of measles. They appear first on the face and the circumoral region is always implicated. The spots spread rapidly over the body and the case then looks more like scarlet fever, especially when the rash has disappeared from the face. The temperature is often absolutely normal. There is usually a slight sore throat and the patient may sneeze a few times. Sneezing is very rare in scarlet fever. The fourth disease as described by Dukes lies between scarlet fever and rubella. The rash covers the whole body in a few hours and is brighter than that of scarlet fever. The throat is swollen and the conjunctivæ are pink. The glands are enlarged as in rubella, the desquamation may be slight or profuse. The tongue is clean or only slightly furred. It affords no protection against scarlatina or rubella. Since a second attack of scarlatina or measles is possible and since the few cases reported might easily have been mild cases of scarlet fever, it seems unnecessary as yet to attempt to differentiate a fourth disease.

Masked Malarial Fevers.—Few physicians have yet learned to appreciate what a variety of obscure symptoms may be present in cases of chronic malarial poisoning. Since the return of our soldiers from Cuba and the Philippines, numerous cases have arisen in all parts of the country and the recognition of this peculiar infection is extremely important. In an analysis of 195 cases of latent and masked malarial fever in which the diagnosis was not made, C. F. Craig (Med. Rec., Feb. 15, 1902) shows how easy and natural it is to make mistakes unless a thorough examination of the blood is made. Symptoms referable to the intestinal tract were most frequently present, the diagnosis of chronic dysentery being made in fifty-five cases. Although the cases showed irregular slight rises in temperature, malaria could not have been diagnosed from the symptoms. Quinine was of marked benefit in all those instances in which the parasites were demonstrated. Pulmonary tuberculosis was another diagnosis frequently made. These cases showed a quotidian rise of temperature and were accompanied by cough, great emaciation, profuse sweats, and presented a picture of pulmonary tuberculosis. Various other diagnoses were made, many of them being correct, but the course of the diseases was modified by a concomitant latent malarial poisoning and could be greatly improved by the elimination of this factor. It is therefore advisable in any obscure or chronic disease, especially when originating in the tropics, that a thorough blood-examination be made. Most of the cases are due to the estivo-autumnal parasite and the knowledge of its presence is especially important for it is this form of the disease which may at any time become pernicious.

Stokes-Adams Disease.—The various symptoms accompanying a permanently slow pulse without heart lesion, which are grouped in the rare condition known as Stokes-Adams disease, are enumerated by L. Azote (La Sem. Med. d. Buenos Aires, Year VIII., No. 45), as observed in a recent personal experience and as reported by other clinicians. The characteristic triad of symptoms are stated to be as follows: Bradycardia, epileptiform and syncopal attacks, the first being the invariable element. Other manifestations are increased arterial tension, absence of valvular lesions with accentuation of the diastolic sound in the aortic interspace coexistent with arteriosclerosis (which latter is thought to play an important part in the pathogenesis of the disease), vertigo, albuminuria, decreased urea, unequal dilatation of the pupils. By many observers insufficient blood-supply to the bulb is thought to be an etiological factor in the condition; this bulbar anemia, in the author's opinion, is probably due to arteriosclerosis.

Hemoglobinuria in Malaria.—It has been a disputed question whether the hemoglobinuria, which is sometimes observed during the course of a malaria, is due to the quinine which has been given or whether it is a modification of the malarial infection. It is also believed that this condition is associated with malaria developed in the tropics and is influenced by alcoholism or other predisposing causes. In contradistinction to this is an interesting case reported by M. Otto (Deut. med. Woch., Jan. 23, 1902). The patient contracted and developed the disease in a northern climate; it ran a course of the quartan type for four weeks uninfluenced by treatment. Then a single dose of quinine (7½ grains) was followed shortly afterward by a severe hemoglobinuric attack. About five weeks later a similar attack followed the ingestion of 15 grains at one dose. The personal predisposition toward the drug seems to be set aside by the fact that the patient had been taking continuous small doses without any such effect; later on steadily increasing quantities were well tolerated. The patient's personal history, climatic conditions, and malarial changes in the blood could it seems be entirely eliminated, and the true cause for the attack assigned to the quinine.

The Source of Fever.—Although it has been demonstrated that an increase in bodily temperature is due to an increase in heat production, it still remains to be shown in what organs the increased heat production takes place. An interesting contribution to this question is made by the discoverer of the heat center in the brain, E. Aronsohn (Deut. med. Woch., Jan. 30, 1902). After eliminating by animal experiments the large glands and the blood as originators of heat, he shows by various devices that the muscles themselves are the true seat of fever production. A further proof is furnished by the following experiment: An animal is brought into a condition of fever by some definite irritant and the entire musculature eliminated as a factor by an injection of curare; this paralyzes the motor end organs in the muscles, but leaves the muscle itself free to respond. In all cases the temperature was found to drop about half a degree in ten minutes. In animals subjected to starvation methods the application of heat irritants produced only the slightest increase in temperature. From his observations the author concludes that fever consists of a pathological irritation of the known heat centers whereby the motor-trophic apparatus of the muscles, both voluntary and involuntary, is stimulated to a greater heat production, an increased metabolism, and a variation in the heat radiation.

How to See Stomach Curvatures.—Various methods of stomach examination have been advocated in order to locate the position of the curvatures. Many of them involve the use of special instruments and necessitate considerable skill. M. I. Knapp (N. Y. Med. Jour., Feb. 15, 1902) suggests a very simple and, as he says, unerring method to determine this point. The patient lies flat upon the back, relaxing his muscles and breathing easily. The examiner stands at the side or at the shoulder of the patient so as to look either up to the stomach region or down upon it. As the patient breathes the examiner follows certain lines which he sees move up and down with respira-

tion. The curvatures of the stomach will be seen as very distinct fine lines moving under the skin even when the wall has considerable fat. A mark is made where the lines stop each time and to corroborate the observation percussion is used by placing the hand flat upon the abdomen, one finger on either side of the above line. If the line of curvature has been properly located a change in note will be found at that point. The percussion should be light and the stethoscope is of great assistance. It may be placed anywhere in the neighborhood of the stomach.

Cardiac Myopragia.—Attention has been called by Prof. Potain (La Médecine Moderne, Dec. 25, 1901) to a peculiar state of unstable biological equilibrium in various viscera. How many people there are who have one or more organs which do their proper work under ordinary circumstances, but rebel against the least extra requirement. This condition Potain called myopragia, and he found it most common in the heart. It is important to recognize such a condition, for a heart of this kind may be much benefited by the daily administration of a granule containing ¼ of a milligram (gr. 1/250) of Nativelli's digitaline.

Transmission of Bovine Tuberculosis.—In an endeavor to record impartially the various data bearing upon the question of the intercommunicability of human and bovine tuberculosis, Adami (Phil. Med. Jour., Feb. 22, 1902) comes to the following conclusions: (1) Bovine tuberculosis is easily conveyed from cattle to cattle; for practical purposes other modes may be neglected. (2) Natural infection of cattle with human tubercle bacilli is extremely rare. (3) Swine are easily infected with both human and bovine bacilli and in very rare cases might act as intermediaries. (4) Bovine tuberculosis can be eradicated even when the human form remains widespread. (5) Human tuberculosis is usually conveyed by inhalation, more rarely through the alimentary or the genital tracts, or by surface wounds, and the bacilli are conveyed from previous cases of the disease in man. (6) The bacilli of man and cattle do not present specific differences, merely racial ones. (7) It is possible to transmit bovine tuberculosis to man through wounds or through the digestive tract; this is usually the case in infants and children. In passing through cattle the bacilli seem to acquire a lessened virulence for man and it evidently requires a large number, especially from extensively diseased cattle, to produce any effect; all animals showing physical signs of tuberculosis or udder disease should be condemned. As a final criticism of Koch's recent address, he laments the manner in which his conclusions were published, in so far as they should not be interpreted to influence in the slightest degree the legislative measures adopted to reduce the danger to cattle and the community resulting from the spread of tuberculosis among domestic animals. In not having done this he left it to be inferred that legislation against bovine tuberculosis is in excess of what is necessary.

Tuberculosis in Infancy.—The diagnosis of tuberculosis in earliest infancy and up to the fifth and sixth years of life affords considerable more difficulties than in adults, says A. Querin (Münch. med. Woch., Feb. 11, 1902). In most cases the disease finds its beginning in the glands and pulmonary involvement follows owing to rupture into a bronchus; hence, the usual site is at the root of the lung and never at the apex. Bronchopneumoniæ following the infectious diseases also frequently lead to tuberculosis and here also, for mechanical reasons, the apex escapes, the lower lobes on both sides of the spine being generally affected. Concerning frequency, hardly any cases have been reported in the first three or four weeks of life and only a few in the first months after birth. Formation of large cavities is not common. Little can be said of symptoms; there may or may not be a slight cough; râles without signs of consolidation occur here and there over the lungs and fever may be slight or entirely wanting. Unfortunately sputum can be obtained only with difficulty for examination, but a trick may here be employed: After an attack of coughing, the index finger, wrapped in sterile cotton, is introduced behind the tongue and sufficient material is thus obtained.

SURGERY.

Nephrotomy in Nephritis.—Renal disease has been considered almost invariably as a contraindication to operative interference of any kind, yet Harrison, in 1896, proposed incision of the kidney in acute nephritis, scarlatinal or otherwise, for reduction of congestion and, in his belief, prevention of chronic nephritis. Edebohls practised decortication for the cure of nephritis. C. Mongour (Jour. de Méd. de Bordeaux, Feb. 9, 1902) reports two cases, apparently hopeless, which were successfully treated by nephrotomy after all other measures had failed. To the class of patients beyond therapeutic treatment the author limits the operation; yet, as a last resource, finds its justification in the fact that autopsy has shown, in many cases, sufficient healthy tissue in the kidney to carry on its function, were it not for the presence of congestion, the relief of which would, in all probability, have averted death, absolute renal insufficiency being regarded as made up as a rule of permanent insufficiency due to the renal lesion and of temporary insufficiency which it is possible to relieve.

Osteitis Deformans.—Only ten cases of this rare disease have been reported in this country thus far. Another is added by J. C. Wilson (Phil. Med. Jour., Feb. 15, 1902), the patient being a male, aged sixty-three years, of good previous history. The history extends through a period of sixteen years, the first symptom noted being an outward bowing of the legs, followed some five years later by a bowing of the forearms, all of which grew progressively worse and were accompanied by an increase in the size of the head and by a kyphotic condition of the spine. The case is minutely described, but no form of treatment was found to be of any avail.

Effects of Cocaine and Eucaine.—A summary of the experimental research of the action of these drugs and the clinical application of the evidences is submitted by G. Crile (Jour. Amer. Med. Assoc., Feb. 22, 1902). A large number of experiments on animals were made in accordance with the idea that the injection of cocaine or eucaine into the substance of a nerve trunk causes an effectual physical block and prevents the passage of all afferent and efferent impulses. They form no chemical combination, but merely suspend the functional activity of a nerve. When applied to the floor of the medulla all the manifest functions of that organ are temporarily suspended, except the heart's action and that is modified. Both eucaine and cocaine block the impulses set up by electrical stimulation even after death. The inhibitory action of the vagi is wholly or partially suspended, and it is probable that the increased rapidity of the heart action is due to the removal of this vagal influence and not to the stimulation of the accelerators. It was also found that dogs under the influence of these drugs endure more exposure and injury of the intestines, without any fall in the blood-pressure than those not so treated. If a series of injections were administered at given intervals, a marked tolerance was acquired, so that finally little effect could be produced. The clinical application of the experimental evidence is supported by a recital of the author's cases. Amputation of the leg below the knee was done

five times with anesthesia secured by "blocking" the external cutaneous, anterior crural, and sciatic nerves. Four operations in the area of distribution of the ulnar nerve and two amputations at the shoulder-joint were successfully done. In all these cases the important point demonstrated was the avoidance of shock, due to the fact that all impulses, whether constituting pain, or controlling vasomotor, respiratory or cardiac mechanisms, are "blocked" or "physiologically amputated." Given hypodermatically, experiments show that these drugs diminish shock in operations on the splanchnic area, and this evidence seemed to be corroborated in two cases of gunshot wounds of the intestines.

Ligature of the Dorsalis Pedis Artery.—There are few arteries which present so many anomalies as the dorsalis pedis. According to the researches instituted by Viannay (La Sem. Méd., 1902, No. 4), the course of this vessel as described by most of the classical treatises is not met in practice in the majority of the cases. Most frequently the artery in question bifurcates at its exit from beneath the anterior annular ligament of the tarsus. The two branches may be of equal volume: the one, the internal, follows the usual course of the normal dorsalis pedis artery, while the other, the external, corresponds to the dorsalis tarsi artery. It is in those cases in which the two branches of bifurcation are of unequal size that the trouble arises. Sometimes it is the internal which is the larger, and hence the typical classical description of most authors. Sometimes it is the external branch which is the greater, while the normal dorsalis pedis on the other hand is rudimentary or at times even absent. Sometimes also the blood-supply of the back of the foot is due entirely to the external artery, which then corresponds to the dorsalis tarsi artery. Such being the case, if one depend entirely upon the typical method of ligating this artery he is in danger of finding only a very small vessel or, perhaps, none at all. He is then compelled to search beneath the annular ligament, which is the only point where the vessel can always be found. Therefore, in order to avoid this useless search, Viannay proposes that the classical incision be extended upward, so that the inferior border of the annular ligament shall be exposed. In this way the artery will always be found, whether it consists of one or two branches at this point.

Poultice Method of Healing Abscesses.—In order to avoid the danger of infection from septic materials used in poultices, M. B. Hutchins (N. Y. Med. Jour., Feb. 22, 1902) advises the use of a three-per-cent. carbolic-acid solution in mixing up the flaxseed and claims that he obtains excellent results without making wide incisions. The poultice is changed frequently, the moisture affording constant drainage and the dressing readily absorbing the discharge. There is often a saving of seventy-five to eighty per cent. of time in healing.

Prevention of Vomiting after Ether Anesthesia.—Believing that the nausea and vomiting after ether administration are due to the irritant effect of the drug upon the gastric mucosa, R. J. Hess (Med. Rec., Feb. 22, 1902) has made various experiments in which the amount of the drug used was diminished as much as possible and the poison diluted before being eliminated. It is known that when sufficient quantity is taken into the blood of animals, its excretion into the stomach and by the kidneys may set up an acute inflammation of these organs. By working along these lines, it was found that the shorter the operation and the less the ether used, the less was the danger of subsequent vomiting. In preparing patients for operation it has been customary to stop all solid foods for at least six or eight hours before the operation and even to diminish the fluids for several hours Again, only very small quantities of water are allowed during the twenty-four hours after the operation. It is believed that these procedures so drain the system of fluids that the ether excreted is in a much more irritating and concentrated form. To avoid this he gives plenty of water up to the time of operation and as soon as the patient awakens from two to six ounces are administered. Very good results were obtained by this method.

Taxis in Obstructed Herniæ.—A warning cry against the use of taxis in incarcerated herniæ is raised by O. Lan (Münch. med. Woch., Feb. 4, 1902) for the intestines are so frequently injured and reduction *en bloc* is effected with so little effort that there is no excuse for employing this antiquated method in these days of aseptic surgery. It is too often found that the symptoms persist after apparently successful taxis and that then an operation much more serious and difficult than a primary herniotomy will become necessary. The hernial sac should always be opened before reduction and local anesthesia may be employed if this is thought best.

Rare Anomaly of Biliary Passages.—The following rare anomaly was found by H. Kehr (Münch. med. Woch., Feb. 11, 1902) during an operation. The gall-bladder was attached to the left lobe of the liver, the cysticus emptied into the narrow left hepaticus, which joined close to the duodenum with the very much enlarged right hepaticus, the course of which was a normal one along the lower edge of the hepato-duodenal ligament.

Position for Gall-Stone Operations.—While attempting to remove a stone incarcerated in the common duct, W. Ruhl (Münch. med. Woch., Feb. 4, 1902) accidentally cut into a large vein, presumably the portal. The vessel could not be grasped owing to the fact that the deep funnel-shaped wound imediately filled with blood which obscured everything and the patient would no doubt have bled to death had not the happy expedient been resorted to of elevating the trunk to an angle of 45°, so that the blood could readily flow out and its source be determined. Not only is hemorrhage more readily controlled by this method, but the parts are rendered more accessible and the relations more nearly approach the normal in all operations on the upper part of the abdomen.

Surgery of the Gall-Ducts.—An analysis of cases of gall-stones treated during a period of ten years at St. Hedwig's Hospital in Berlin shows that 41.5 per cent. of the cases treated medically were cured, while surgical interference was successful in 98 per cent. of the cases in which it was practised. The surgeons in this institution, says H. Scheuer (Berl. klin. Woch., Feb. 17, 1902), have come to regard excision of the gall-bladder as the normal surgical procedure for the treatment of gall-stones. In a number of cases which this writer describes in detail, cholangitis essentially determined the clinical picture. One patient had high fever, pain in the hepatic region, liver enlarged downward, and marked icterus. Aspiration was performed over what was assumed to be the region of the gall-bladder, the needle being passed inward about 6 cm.; bile without pus was withdrawn. Laparotomy was begun at once to prevent as far as possible the escape of bile into the peritoneal cavity. The gall-bladder proved to be small; the common duct was not enlarged; the liver was much enlarged, and the aspirating needle had penetrated into the hepatic substance. Renewed puncture of the parenchyma of the liver resulted as did the original puncture. The diagnosis was therefore cholangitis with closure of many smaller biliary passages, the main ducts being free. Cystostomy would here have been valueless. By means of the Paquelin cautery, a six-inch incision was made directly into

the parenchyma of the liver; a large biliary duct was met, from which bile isued with great force. The operation was very successful. At first the bile was discharged almost wholly through the wound; but from the tenth day after the operation the stools resumed their normal color and the icterus rapidly disappeared. According to Scheuer, no similar operation is described in the literature, although Hirschberg at the last International Medical Congress recommended this procedure in the treatment of hepatic cirrhosis. The operation is evidently not followed by the serious hemorrhage which might be anticipated.

Gastric and Duodenal Ulcers.—In the current text-books on medicine one finds a bewildering number of theories touching on the etiology of these conditions; none are supported by adequate evidence; some of the most favored, according to C. R. Box (Brit. Med. Jour., Feb. 8, 1902), are as follows: (1) Arterial thrombosis; (2) embolism; (3) endarteritis obliterans; (4) simple spasm; (5) mechanical injuries; (6) diminished alkalinity of the blood; (7) microbic infection of the lymphoid follicles of the stomach-wall. This last is the most recent theory and for the following reasons seems to have a very practical bearing: (*a*) For any part of the intestinal tube below the duodenum the theory of the infective nature of ulceration is at once accepted. Typhoid, tuberculous, and dysenteric ulcerations are unanimously attributed to an infective cause. The same holds for ulcerative colitis and the destructive process in appendicitis. (*b*) The fact that it is not uncommon to find that ulcers both in the stomach and in the duodenum may be multiple, and not only multiple, but so placed—either exactly opposite or quite close to one another—that infection from one to the other may have easily occurred. When two ulcers are placed opposite to each other, it is said that close examination will often show that one is an older ulcer than the other. These opposed ulcers have repeatedly been met with postmortem, not only in the stomach but also in the duodenum. (*c*) The appearance of a recent acute ulcer at the time of operation for perforation is itself highly suggestive, and it was this appearance which first seriously directed attention to the microbic theory. Such an ulcer is always surrounded by a zone of highly-edematous and softened tissue of considerable extent. Stitches easily tear through the edematous wall, and so considerable difficulty may be experienced in applying the sutures. Every surgeon who has had much experience in the suturing of acute perforated ulcer recognizes this edematous condition. That gastric ulcer is a disease of great latent danger is shown by the fact that a large percentage of ulcers perforate with fatal results without giving warning of their existence by any other symptoms than vague dyspeptic pains. Hematemesis and melena, which will probably for a long time to come be the only pathognomonic signs of gastric and duodenal ulceration, are often lacking. The differential diagnosis of gastric ulcer must be made, first, from renal disease; second, from locomotor ataxia; and, third, from hysteria. These latter cases fortunately are rare. The blood is obtained by injuring mucous surfaces, such as the mouth or vulva. These patients often mix their urine with their vomit and indulge in other fraudulent methods which are as interesting to watch as they are difficult to trace. A last possible point in establishing a differential diagnosis in these conditions lies in remembering that hematemesis occasionally occurs in mitral disease. Although ulceration is much more frequent on the posterior walls of the stomach, perforation with general peritonitis more often occurs anteriorly. This is due to the protection afforded the retrogastric space by the lesser peritoneal cavity. It is necessary in all cases of perforated ulcer, whether they have been operated on or not, to keep a very careful outlook for localized collections, the most frequent sites of which are in the lesser sac, subphrenic, perisplenic or pelvic. In conclusion, then, a diagnosis of ulcer should be established positively only on the occurrence of hematamesis or melena; tentatively only after a consideration of the following points: (1) The patient's statement as to hematamesis should be received with reserve and corroborated. (2) In doubtful cases it is necessary to see the vomited materials one's self if this be possible, and, better still, to observe or have observed the actual act of vomiting. (3) In all cases the urinary examination should be a routine procedure. This examination should be thorough, and include the search for casts as well as for albumin. A single examination is often not enough. (4) The eyes should always be examined, particularly with a view to the presence of the normal light reflex, and the occurrence of changes in the fundus. Optic atrophy may put one on the track of locomotor ataxia; the presence of optic neuritis may reveal an unsuspected cerebral tumor, and the presence of neuroretinitis may indicate renal disease. (5) An examination of the stomach-contents for the presence of excess of free HCl should always be made when practicable, and if the first examination be negative a second should be undertaken before one can be sure of its absence. Hyperacidity is a valuable, although not absolutely constant, sign of gastric ulceration. (6) Every patient in whom gastric ulcer is diagnosed should be looked upon as seriously ill. The disease is commonly treated much too lightly, considering its liability to such serious and fatal complications. Prolonged rest in bed and proper dieting for some time are essential in all early cases.

Gold Sutures.—The advantages of gold sutures are especially urged in operations for hernia. I. Tansini (La Riforma Medica, Jan. 18, 1902) states that the character of the sutures used is frequently responsible for suppurative conditions occurring after operations for the radical cure of hernia. The advantages claimed for the gold suture are that it can be drawn out to a very fine thread, being superior to silver in this respect; it can be readily and thoroughly sterilized; it is flexible and resistant, and as easy of application as silk thread; it is more rapidly fastened by a simple twisting of the ends, rather than tying, as in the case of the silk suture.

EYE, EAR, NOSE, AND THROAT.

Climate or Spectacles?—Under this title attention is drawn by G. S. Hull (Ophthalmic Record, Jan., 1902) to cases of neurasthenics sent to Pasadena for rest who apply for glasses to relieve them of the discomfort they feel in the brighter sunshine of California. He notes that when he has fitted them suitably for refractive errors, not only are they relieved of the trouble from increased sunlight, but they are also relieved of that for which they were sent from the East, *viz.*, their neurasthenic symptoms; and he very pertinently asks, "Climate or spectacles, which?" leaving the answer to be given by the physicians in the East.

Perforated Disk in Subjective Testing of the Refraction.—In using a mydriatic the disadvantage is in the enlargement of the pupil; a desideratum would be a drug which would paralyze accommodation and not affect the pupil. F. B. Eaton (Ophthalmic Record, Jan., 1902) advocates the use of a disk with 4 mm. perforation for distance and 2½ mm. perforation for near to confine the rays of light to what he prefers to call the natural dioptric path, called by Jackson the "visual zone." He claims to avoid errors in astigmatism and to arrive easily at the meridian of least refraction.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 22, 1902.

THE PROPOSED PRIVATE SMALLPOX HOSPITAL.

So much has appeared of late in the daily papers concerning the necessity of a private hospital for well-to-do smallpox patients that an interview with some of those gentlemen who are of necessity most conversant with the subject must be interesting and to the point.

Dr. George T. Stewart, the superintendent of Bellevue Hospital, who comes into very close contact with this type of work and who is a recognized authority in hospital management, spoke most emphatically on the subject. He said in part that there were several important reasons which seemed to him paramount, and which, when subjected to calm criticism, could lead but to one conclusion. The psychical factor is always paramount. Under this the friends and family are first to be considered. The effect of a new environment on the patient himself. For some reason or other the separation by water from loved ones afflicted with smallpox seems to be peculiarly dreaded by most people. So far as the effect on the patient goes, it is not without important medical significance, for for one accustomed to a comfortable environment it is by no means propitious to be cast suddenly into an entourage designed to fill the needs of our more humble citizens, this being the character of the accommodations which are given to all at North Brother Island.

"What do you think would be the effect upon you or me," said the affable superintendent, "if we were taken from our comfortable quarters and obliged to wear the garb, to eat the food, to sleep in the bed, to see the sights, and to hear the sounds to which our gentle organs are unaccustomed? The psychical effect upon such patients on visiting North Brother Island is of necessity somewhat similar to that which would be observed in us if we were put up in the penitentiary and obliged to wear the medieval hob-nailed shoes which characterize the chief terrors of that institution." So far as the administration of the North Brother Hospital goes, Dr. Stewart says that, considering the funds meted out by the city for the purpose, the patients get fully as good care and about the same type of food as are given at Bellevue and the other city hospitals. It is in the nursing staff, however, that the hospital is unfortunately crippled. Even among professional nurses the idea of smallpox is still the ancient one, namely, that it is a noisome disease of a most filthy character. Where there are so many other openings for professional nurses, who, notwithstanding their many virtues, are rather hedonistic than altruistic as compared with the old-fashioned Sisters of Charity, it is very difficult to get a good nursing corps. Dr. Stewart believes that $100,000 has been promised to the City, but feels that the chief difficulty in the acceptance of this donation is that the Board of Health is not empowered to run such an institution until the funds from private sources are adequate to cover all its running expenses. Dr. Stewart said, "You may quote me as saying anything and everything in favor of our having such a hospital as is proposed."

Dr. Hermann M. Biggs, while not as cordially in favor of the project as Dr. Stewart, would certainly offer no objection to the proposed hospital. He said, however, that there were much more crying needs for a modern hospital with suitable equipment to care for the poor children of the Borough of Manhattan who were afflicted with measles and scarlet fever, the present accommodations being quite inadequate. As to the gift of $100,000, that would be a mere drop in the bucket; the cost of the land would be at least $250,000, the only suitable site in the Borough being at the foot of East Sixteenth Street, and the building itself would cost an additional $100,000. This

might all be readily compassed, particularly if some rich people failed to get vaccinated, but the main difficulty is that such an institution would need an endowment fund which would yield an income of $150,000 a year. Such a hospital is extremely expensive to run because among the rich, at least, smallpox is essentially epidemic rather than endemic in this city and most of the sporadic cases would continue to be cared for by public charity. For months at a time the hospital would be empty, but its expenses would continue, for the staff must of necessity be permanent. Even in epidemic days, the income from the rent of rooms, which under any conditions would have to be almost extortionately high, would not begin to defray a tithe of its expenses. Furthermore, it would not be possible for the Health Board to assume the control of a private smallpox hospital and go into the business of renting rooms without obtaining special legislation from Albany. "Let the rich people be vaccinated," said the doctor naïvely, "and there will be no occasion for any such institution."

ANTIVIVISECTION ONCE MORE.

The Zoöphilists of Boston in their annual engagement at the Massachusetts State House are now presenting the notorious melodramatic extravaganza "Antivivisection" despite the recent striking failure there of the much more serious entertainment entitled "Antivaccination"; the two companies are not altogether identical, but similar at least in their general attitude of opposition toward our public medical institutions.

The bill which these hysterical or else sciolistic people have presented to the Legislature for hearing before a committee is somewhat less drastic and so less harmful than those of former years, it being obviously its framers' intention, clearly avowed in part, to use it chiefly as the entering end of a wedge which as soon as possible shall entirely prohibit animal experimentation. The petitioners base their bill on the possibility that abuses in vivisection may exist in the future, which possible abuses are to be severely punished, as indeed were meet, when they shall have been detected by the "agents of the societies for the prevention of cruelty to animals." The counsel for the petitioners, in a recent session, said, "It is not necessary for our purposes to show that abuses do exist. It is enough to show liability to abuse." To this deliberate statement of policy the chairman of the legislative committee naturally objected very strenuously, and, indeed, it is the most striking feature of all these misguided hearings that, despite the openness of all physiological laboratories (except to newsboys and intoxicated persons perhaps), *no evidence of any cruelty whatever has ever been presented and substantiated* The committees of the Legislature of the Commonwealth visit the laboratories, see exactly what is going on therein, and forthwith unanimously give the petitioners prompt "leave to withdraw."

The two paragraphs of this year's proposed bill which are most objectionable to the cause of medical research read as follows: "Every animal subjected to such experiment shall be killed immediately upon the conclusion thereof and while under the influence of the anesthetic"; and "The authorized agents of any society for the prevention of cruelty to animals incorporated under the laws of this Commonwealth shall be permitted to enter any place registered as required by Section 1 hereof, at any time, without previous notice, and to take the name and residence of any person found therein." (The Society for the Prevention of Cruelty to Animals, however, has little or nothing to do with this movement, fully aware as it is through its agents that no cruelty exists.) The former of these requirements would, if it were law, prevent the legal performance of some of the most important of experimental operations, as any fairly informed person will instantly appreciate. The latter of the quoted paragraphs would make all scientific surgical experiments at least impracticable, since it would render any such operation liable at any time to gross interruption through the noisy entrance or ignorant supervision, or both, of men such as these societies do and would employ as their agents—retired policemen, superannuated janitors, or other unsympathetic laymen hired for a purpose at fifty dollars a month. What physiologist or pathologist or chemist would care to begin a research consisting perhaps of a long series of delicate surgical operations, likely as not with the simultaneous management of a complicated recording apparatus, under such conditions as these!

Thus the present proposed bill practically would prevent, if passed, what are perhaps the most valuable researches of our modern physiology, etc., while it would put into practice a system of espionage quite at variance with the noble standard of the profession of medicine. We shall look for a denial to this petition at least not less prompt and emphatic than its predecessors have received.

THE BLACKWELL'S ISLAND PHTHISIS HOSPITAL.

The much-discussed question of the care of the City's indigent phthisis cases has for some time past agitated the lay and medical journals, but until recently nothing tangible has been accomplished. It would seem that the problem were either outside the realm of possibility, or that the City officials were not sufficiently aware of the urgent necessity for active measures.

The new Commissioner of Public Charities, Mr. Homer Folks, has made the first move in the proper direction in transferring the tuberculous patients of the charity hospitals to one of the old buildings on Blackwell's Island, which was formerly occupied by the Manhattan State Hospital for the Insane. This, however, is but a prophylactic measure for a disease which in the past has wrought havoc among the non-tuberculous inmates of the various institutions devoted to the care of the sick poor. It has no bearing on the cure of the transferred patients, who were much better cared for in their former surroundings, in which they had the cheering influence of the other patients. In their new quarters they are in small cell-like rooms, shut off in many instances from the sunlight, to await the coming of the end.

This old insane asylum, as might naturally be conjectured, was not designed for the purpose it is now to serve, but was constructed for the care and restraint of the insane. Many of the rooms were really cells with barred windows and paneled doors. Such surroundings can only add to the already depressed mental condition of the tuberculous sufferers.

Commissioner Folks has asked the Board of Apportionment for eighty-eight thousand dollars to renovate these buildings, that they may be made suitable for the treatment of incipient cases as well as to furnish a home for the already doomed ones. Forty thousand dollars of this amount will be expended in the actual renovation of the building and in the construction of glass pavilions where the incipient cases can be scientifically treated by the latest approved methods.

It is the intention to devote the sum of five thousand dollars toward the remuneration of an efficient corps of doctors and nurses. To use a Hibernian hyperbole, such a proposition would be amusing were it not absolutely ridiculous. In the pavilion now occupied there are only one hundred cases. When the other four buildings are renovated there will be accommodations for an additional four hundred patients, making the total capacity of the institution five hundred. With a physician to every hundred patients and a nurse to every twenty, at least five physicians and twenty nurses must be employed. The City pays its nurses on an average fifteen dollars a month. The twenty nurses would then so nearly consume the five thousand dollars that the physicians would have to contribute their valuable services for sweet charity. The Department will encounter no little difficulty in finding men who are willing to subject themselves to the constant danger of infection in return for the reward of board and lodging and one afternoon a week.

It is estimated that the five hundred patients can be maintained at a cost of eighteen thousand dollars annually. This is to include board, lodging and clothing. If the patients are to be cared for after the fashion of the rest of the City's hospital charges, the sum proposed will be more than sufficient. Congratulations are due to Mr. Folks for the interest he is taking in this matter. He is the first of his line to take up arms for the protection of the pauper "lunger" by endeavoring to plan and carry out some practical measure for his care and cure.

Judging from the experiences of previous charities commissioners who have made efforts to institute changes along scientific lines, the application for this modest sum of eighty thousand dollars will meet with opposition. It is probable that the knowledge of this fact has led the Commissioner to ask for the small sum, which is obviously inadequate.

While we cannot expect the Board of Charities to grant more than this, we at least hope that Mr. Folks will get the whole sum required. For with such an amount at hand he will be able to create the nidus of a future model phthisis sanitarium; and the old adage, now too true, that only the rich may hope to recover from the deadly grasp of the tubercle bacillus will then happily become a saying of the past.

ANIMAL EXPERIMENTATION.

A little book which cannot fail to be of interest to all medical people, to the Massachusetts legislators and to their constituents, indeed, to every person interested in medical progress (and who that is mortal is not one of the latter class?), was recently published in Boston.

The title in full of this widely-useful volume is "Animal Experimentation: A Series of Statements Indicating Its Value to Biological and

Medical Science." Dr. H. C. Ernst is to be thanked for the publication of this collection of expert opinions, he having collected them and attended to their appearance in a form available to the public.

The quotation of a considerable part of the Introduction will make clear the sources of the material of this book and the reasons for its existence. "The following are the statements of various remonstrants to proposed legislation to further restrict experimentation upon animals for medical and biological purposes in the Commonwealth of Massachusetts. They were called out at the legislative hearings upon this subject in the spring of 1901. The agitation in favor of such further restriction has been carried on for several years, and the views of the remonstrants are nowhere to be found in print. Many of the friends of research have expressed a wish to have some document to which reference may be made for the facts of the case, and it has therefore been decided to publish this book . . . It is hoped that the statements that follow will be of value in placing the matter of experimentation upon animals, for purposes of teaching and investigation, in a clearer light before those interested in the subject."

Among the competent and noteworthy opinions quoted are those of Bishop Lawrence, President Eliot of Harvard, President Capen of Tufts, President Hall of Clark, and Drs. H. P. Bowditch, Wm. T. Sedgwick, J. S. Kingsley, M. H. Richardson., J. J. Putnam, W. T. Porter, W. T. Councilman, Theobald Smith and H. C. Ernst. Besides these names, known over the land, sixteen others, clergymen, teachers, surgeons, physicians, all notable in the ranks of the sincere and trustworthy, contributed to this unique volume, destined to have great influence in combating this particular neuropathic menace to the public weal.

Among the more notable contributions are the remarks of Prof. Sedgwick of the Massachusetts Institute of Technology, Prof. Kingsley of Tufts, and Profs. M. H. Richardson and Theobald Smith of Harvard. Professor Porter of the Harvard Medical School supplies twenty-four pages—which constitute in themselves a powerful document, an article of the precise sort which, wide spread in the magazines of large circulation, would soon do much to educate an apathetic public so that even in Massachusetts (often deemed the home of the manifold antimania) this annual annoyance to legislators and to scientists alike would soon die out in the face of a public opinion sufficiently interested to declare itself. The séances of the present year's "agitation" have already begun at the State House on Beacon Hill.

ECHOES AND NEWS.

NEW YORK.

Brooklyn Medical Club.—Professor E. W. Scripture of Yale University will deliver the annual lecture of the Brooklyn Medical Club at the Medical Library Building, 1313 Bedford Avenue, March 24, 1902, at 8.30 p.m. His subject will be, "A Chapter from the New Psychology; Recent Researches on the Voice," with the exhibition of lantern slides, experiments and other illustrations.

A Sound Position.—We approve most heartily of the following comment made by the "Sun" of last week, and might well hope that all of our "lay" contemporaries were as rational in their editorial expressions regarding medical topics: "One Cadin, an Assemblyman, has introduced a bill for the creation of a State commission 'to investigate into and report on the history, nature and pathology of smallpox and also of vaccination as a preventive of the disease.' There is no excuse for pandering in this fashion to ignorance and quackery. There is no doubt as to the efficacy of vaccination in limiting the ravages of smallpox. It has stood the test of a century. It has been accepted by the great mass of the public as well as by men of science. An investigation of this sort can only tend to confirm those who are prejudiced in their folly. Let us not have any legislation of the sort which has taken down the bars of England, for example. The individual has the right to hold all sorts of silly views. But he has not the right to become a danger to his neighbor."

Compulsory Vaccination Law not Wanted.—At a meeting of the Board of Health last week its three members, Dr. Lederle, Dr. Doty, and Police Commissioner Partridge being present, a resolution was passed declaring against compulsory vaccination in any form. The resolution stated that in the opinion of the Board the passage of any bill requiring compulsory vaccination was unwise and uncalled for. The members were agreed that the measure now in the Senate and Assembly Committees was special legislation against all local boards of health and implied that these local boards were incapable of conducting their own department. The members believed that vaccination should be taught not by force but by education, and that it could not afford to have the present harmonious relations between the Board and all classes in the city upset by any mandatory legislation at Albany.

Dr. Knapp's Seventieth Birthday.—Dr. Herman Knapp celebrated his seventieth anniversary Monday last. Dr. Knapp was the founder of the New York Ophthalmic and Aural Institute. He was born in Prussia in 1832, and was graduated from Giessen University in 1854. He was professor of ophthalmology at the University of Heidelberg from 1864 to 1868, and since 1888 has held the same position at the College of Physicians and Surgeons in this city. It was at Dr. Knapp's suggestion that the institute of which he was the founder will move from its present location, No. 44 East Twelfth Street, to the northwest corner of Sixty-fourth Street and Central Park West. Of the new plans for the new institute it is said that the trustees have given their consent to his proposal that the institute should be moved and should be modernly

equipped. The members of the Board of Trustees have subscribed $100,000, which will make one-half of the purchase price of the lot on the Sixty-fourth Street corner. About $400,000 more is needed to build the new institute. This amount must be raised by voluntary contributions. The amount should be subscribed and the building constructed in three years.

Board of Managers of Craig Colony.—Governor Odell has nominated to be managers of the Craig Colony for Epileptics: Dr. Pearce Bailey of this city, Mary E. Joy of Syracuse, Abbot Law Dow of Brooklyn, Jeanette R. Hawkins of Franklin County, George L. Williams of Erie County, and James H. Loomis of Wyoming County.

Trustee of State Hospital for Tuberculosis.—Dr. John H. Girdner of this city was nominated to be a trustee of the State Hospital for the Treatment of Incipient Pulmonary Tuberculosis, to fill the vacancy caused by the resignation of Norman S. Dike.

Appointment of Dr. Kerley.—Dr. Charles Gilmore Kerley has been appointed attending physician to the New York Infant Asylum, West 61st Street and Amsterdam Avenue.

New Claimant for Journalistic Honors.—The "American Medical Journalist" is the title of a newly-launched periodical devoted to the interests of medical advertising. The first number is bright, entertaining and full of instruction. If the succeeding numbers are as interesting as this one, we predict success to the new enterprise and wish it prosperity.

PHILADELPHIA.

Visiting Nurse Society.—At the sixteenth annual meeting of the Philadelphia Visiting Nurse Society, held March 14th, all the officers were reelected. During the past year two new branches have been opened, one in Germantown and the other on South Tenth Street, there now being the central office and four branches. A fifth branch in West Philadelphia is contemplated. The Society aims to give the poor and those of moderate means the best nursing obtainable, the charges for daily visits being only nominal.

Eye Hospital in Straitened Circumstances.—The Wills Eye Hospital which is under control of the City Trusts is in need of repairs, new instruments, etc., and the income from the estate is not sufficient to meet even the running expenses. It has been necessary to reduce the number of patients and as a consequence the hospital is not doing the work it was intended to accomplish; $5,000 is needed for immediate use.

Ground Broken for Hospital Addition.—Ground was broken March 13th for the proposed addition to the Samaritan Hospital. The addition is for the two-fold purpose of supplying needed room for the growing demands upon the hospital and of furnishing facilities for instruction to the students of the medical department of Temple College.

Dr. Morse Visits Philadelphia.—Dr. John Lovett Morse, of Boston, addressed the Pediatric Society March 11th on "Some Diseases of the Kidneys and Bladder in Infancy." A reception at the Aldine followed the address. Dr. Morse also addressed the students of Jefferson Medical College during the day.

Spring School of Medicine to be Established at the University of Pennsylvania.—A matter of no small interest to the medical profession of the Eastern, Middle and Southern States, is the decision on the part of the Medical Department of the University of Pennsylvania to inaugurate, during the coming spring, a series of courses for practitioners of medicine. This movement has been under contemplation for some time and is just now to be consummated. The reasons for and purposes of the spring school are set forth in the last report of the Provost in these words: "The many advantages possessed by a large medical school in promoting and teaching the science and art of medicine, make it desirable that others than undergraduate students should be admitted to its benefits. There exists a body of physicians who, either because their professional lives are spent away from active medical centers or because of original defects in their training, find it difficult or impossible to keep in touch with the progress of medicine. For such of these physicians as may desire to extend, complete, or revive their past training, a graduate course of study would be of great advantage. The medical school possesses, moreover, the equipment needed to supply such instruction. The facilities provided by hospitals are at command throughout the entire year, and those of the laboratories may also be made available." Courses of instruction will be offered in medical chemistry, anatomy, physiology, bacteriology, pathology, clinical medicine and surgery, gynecology, ophthalmology, otology, dermatology, laryngology, and other specialties. All the courses have been designed to be practical in character and to fit the abilities and purposes of the practitioner of medicine. Summer schools for post-graduates in medicine are conducted in connection with several other medical schools, but with one or two exceptions the faculties take a minor part in the teaching, this work being left to the junior staff. This fact is significant in view of the prominent part to be taken by the Medical Faculty of the University in the proposed spring school.

CHICAGO.

Visiting State Institutions.—Dr. John R. Neely, Medical Director of the Institutions at Dunning, is visiting the State institutions throughout the East, particularly Boston, New York and Ohio. He is in quest of information in regard to the way similar institutions are operated before deciding upon certain changes which he has in contemplation at Dunning. After his return Dr. Neely will make recommendations to the County Board, and probably make certain demands of the Civil Service Commission. He will have entire charge of the professional end of the institution, separating the business from the professional work of the physicians and nurses. This has been thought advisable by the County Board, and will doubtless increase the efficiency of the institution.

Dr. Murphy Honored.—The highest honor in the gift of the University of Notre Dame and perhaps the most highly-prized honor that can be attained by a Catholic layman in America, namely, the Laetare Medal, has been conferred this year on Dr. John B. Murphy, of this city, in recognition of his merit as a Christian gentleman and his great work in medical science.

Trust Deed to Secure a Loan.—The Hospital of the Holy Family of Nazareth has given a trust deed to secure a loan of $50,000 for five years. The building is nearing completion, and when completed will have cost, it is said, in the neighborhood of $400,000.

Promotion of Dr. Shepard.—Dr. John L. Shepard, Acting Assistant Surgeon, U. S. A., has been made first lieutenant and assistant surgeon in the regular establishment.

Resolution on the Death of Dr. Fenger.—At a meeting of the Physicians' Club of Jacksonville, the following resolution was passed: "*Resolved*, That in the death of Dr. Christian Fenger, of Chicago, the medical profession has lost a member whom it delighted to honor; one whose work, like his life, was confined to no one land or tongue, but was as cosmopolitan as the fraternity he honored with his name; a great surgeon

pathologist and teacher; one of whom it might fittingly be written, *Doctores docuit.*"

Chicago Medical Society Adjourns out of Respect for Dr. Fenger.—This Society met at the usual hour, March 12th, after which a motion was made that a committee be appointed to prepare for a memorial meeting in honor of Dr. Fenger, to be held some time in April. The Society then adjourned, without taking up the formal program.

Importance of Rickets in Girls from an Obstetrical Standpoint.—Dr. Charles S. Bacon read a paper on this subject before a recent meeting of the Chicago Academy of Medicine. Rickets is a common disease of infancy. Its most serious results so far as girls are concerned do not manifest themselves till the child-bearing period. It is estimated that from 3 to 7 per cent. of all women have contracted pelves due to rickets. Cases are given to illustrate the importance of a pelvic contraction of one to two centimeters. Concerning the etiology of the disease, the effects of insanitary surroundings, improper food, gastro-intestinal disease are acknowledged, but the essence of the trouble is not yet determined. Among the food deficiencies, lack of fat is undoubtedly the most important. The most common pelvic deformity is the simple flat pelvis. This is caused by the weight of the trunk when the child is in the sitting or standing position. The soft bodies of the sacral vertebræ are crowded forward between the wings of the sacrum contracting the anteroposterior diameter. The strong sacro-iliac ligaments pull backward the posterior margins of the ilia and because of the anterior fixation of these bones at the symphysis the transverse diameter of the pelvis is increased. The indications for the treatment of rickets in its acute stage are to control the disease process as soon as possible and to prevent the pelvic deformity. The disease process is corrected by dietetic and hygienic management. Gastro-intestinal infection is overcome and the child placed in as good sanitary surroundings as possible. Fat, which is often lacking in the diet, is given, often in the form of cod-liver oil. The question of the prevention of pelvic deformity is new. Its importance has been overlooked by orthopedists. It is very difficult to keep the child in the horizontal position. If it is possible to devise apparatus which will take the trunk pressure from the sacrum it would be a valuable device.

Relation of Evolution to Infection, with Special Reference to Venereal Diseases.—In a paper on this subject, Dr. G. Frank Lydston presented in detail his views on the variability of pathogenic organisms and their effects, explained by their tendency to revert toward a less highly specialized form (atavism), a principle well understood by students of evolution. The general rule governing such variation may be stated in the formula: The tendency to variation of any species is in inverse ratio to its degree of specialization by evolution. Micro-organisms, being among the lowest and simplest forms of life, are little specialized, relatively, and are consequently subject to wide variations in their pathogenicity. The gonococcus is not always the same organism in its capacity to cause a specific urethritis. Indeed, the gonococcus may be found in the urethra without its having ever excited any inflammatory reaction; in other words, "the gonococcus is not always the gonococcus." The same fact is true of the diphtheria bacillus, the diplococcus of pneumonia and numerous, if not all, other pathogenic micro-organisms. Every disease germ is subject to modification in its disease-producing capacity by its environment, by the suitability of the soil upon which it grows, whether in test-tube culture, or in the tissue soil of its victim. This tissue soil in any individual may be so unfavorable, by reason of a natural immunity or resistance possessed by him, as to render the germ relatively or absolutely harmless. One has to recognize, then, in the power of germs to produce disease, the two factors of the variability of germ species, and the resistance offered to them by unfavorable tissue soil in the individual. The interrelation by these two factors determines the degree of infection. This variability in the capacity of germ species to cause disease has not yet been grasped by the medical profession, though bacteriologists and pathologists are beginning to reckon with it. There is nothing novel or iconoclastic in accepting this doctrine. It is simply the application of the principles of evolution and involution to germs, and to germs these principles apply with particular force because germs are little specialized and therefore poorly fixed species.

CANADA.

Ontario Medical Council.—Session of the Ontario Legislature has closed, but there will be no changes in the composition of the Ontario Medical Council made this year. The proposed amendment of Dr. Jessop to the Ontario Medical Act has not materialized. Instead of recommending its adoption, the special committee of the House to which it had been referred presented a report on the matter which has been received and adopted. This report provides that the Government shall undertake to submit, to the medical practitioners of Ontario next fall, questions, answers to which will afford definite information upon those points which have now been so long in dispute, namely, the constitution and representation of the Council. The answers will then be submitted to the Government and, should there appear to be any decided call for a change, the matter will be acted upon by the next Parliament. The report also proposed that those practitioners who had neglected or refused to pay their annual assessments to the Council should continue to exercise their franchise should occasion arise the same as those who had paid their fees.

New Civic Hospital for Montreal.—The Montreal City Council has at last, after long delay of many years, decided to erect a new Contagious Diseases Hospital. The question was brought up in Council last week by the reading of a letter addressed to that body by the Roman Catholic Dignitary, Archbishop Bruchesi. The new hospital will be erected on Fletcher's Field, will be for infectious diseases other than smallpox, the present Civic Hospital being kept for that purpose, will cost $50,000, and will be strictly non-sectarian. The Catholic population of the city wanted two hospitals, one for themselves and one for the Protestants, but the City Council was almost unanimous for a non-sectarian institution. The Archbishop states he will not accept for his people a non-sectarian hospital.

Chances for the American Medical Students at McGill.—According to a circular letter recently issued by the Registrar of the Medical Faculty of McGill University, Dr. Ruttan, there are some sixty original vacancies in the United States Army, owing to extensions of the Army Medical Service system. These will be filled by competitive examination and Dr. Ruttan wishes that the American medical students at McGill be given a chance at these positions, as there are a number of students at that famous university who hail from the Republic to the south of us. It is understood that several of these will compete.

Victorian Order of Nurses.—In Ottawa last week the Board of Governors of the Victorian Order of Nurses held their annual meeting. The reports submitted showed that the most important work done in connection with the Order during the past year had been the collection of $25,000, raised almost entirely by

the efforts of Lady Minto alone, for the Lady Minto Cottage Hospital Fund. Of this sum some $6,000 has already been spent on the construction of hospitals in the Canadian Northwest Territories, and a further sum of $8,000 has been set apart for similar purposes. During the past year two new branches of the Order have been established, one at Pictou, N. S., and one at Dauphin, Man. In Pictou a wing of the Marine Hospital is now supplied with nursing service by the Victorian Order, whereas before no nursing was available. The financial report stated that there was some falling off in the endowment fund of $2,500 which is collected annually.

Tuberculosis in the Province of Quebec.—The Recorder of Vital Statistics for the Province of Quebec, Dr. Paul E. Prevost, states that in the year 1897 there were 3,079 deaths in that Province from tuberculosis; in 1898, 2,876; in 1899, 3,085; in 1900, 3,015. These figures show the death-rate from tuberculosis to be three times that of any other disease, except infantile diarrhea. There occurred in Montreal alone 791 deaths from consumption in 1900, which was 10.32 per cent. of the deaths from all causes. The whole subject of tuberculosis is to come up for discussion in the Legislature of the Province. A member of that body has asked that the Government produce all correspondence and documents in its possession bearing on tuberculosis, its prevalence, and treatment. Efforts will be made to secure financial aid for sanatoria the same as is provided for in other Provinces of the Dominion, namely, Ontario and Nova Scotia. Quebec Province has a good sanatorium, the Laurentian, but it does not receive any aid from the Provincial Government. This is situated at St. Agathe des Monts, a short distance from Montreal, and is superintended by Dr. Arthur J. Richer of that city.

Proposed Dominion Medical Council.—When Dr. Thos. G. Roddick, M.P., closed his address last week in the Canadian House of Commons, in moving the second reading of his bill for a Dominion Medical Council, he received the applause of both sides of the House. A member from Quebec objected to the second reading of the bill as he doubted the constitutionality of the measure, and some one also stated that Laval University was opposed to the principles of the bill. The Premier, Sir Wilfrid Laurier, stated that as Dr. Roddick had asked that the bill be referred to a special committee of the House after it had received its second reading, he would not then oppose it. This action of the Premier is considered in some quarters to be a hint that when the bill comes before the House for its final reading, he will instruct his followers to oppose it. If that be the case the long and arduous labors of Dr. Roddick in the cause of the medical profession in Canada will have proved futile. As the bill now stands it provides for a Council of thirty-nine members, as follows: Eight from the Province of Quebec, Laval University to have an additional College representative; nine from Ontario; four each from Manitoba and Nova Scotia; three each from New Brunswick, British Columbia and the Northwest Territories; two from Prince Edward Island; three from the Homeopathic body. The proposed bill has received the endorsation of all the Provincial medical societies and of the national medical organization, the Canadian Medical Association. Surely the Dominion Parliament has the power to elevate the medical profession of Canada and give it a national standing.

GENERAL.

Post-Graduate Study in Baltimore.—The College of Physicians and Surgeons of Baltimore has instituted a series of post-graduate courses in medicine, surgery, medical and surgical specialties and in laboratory work in pathology, bacteriology and pharmacology. This is a new departure for this institution.

Prophylaxis of Tuberculosis.—Among protective measures proposed by the Association for Defence against Tuberculosis in Milan is the general distribution of cards bearing the words "Do not expectorate upon the ground." It is also advised that such a placard be exposed in the churches.

German Surgical Congress.—The Thirty-first Congress of the German Society of Surgeons will be held in Berlin, April 2-5, 1902.

The "Cleveland Medical Journal."—The first number of the union of the "Cleveland Medical Gazette" and the "Cleveland Journal of Medicine" has been received and we congratulate the profession of Cleveland on its splendid appearance. As an exponent of a united profession in the city of Cleveland it is also the more welcome to the ranks of high-class medical journalism. Long may it prosper and the principles of its incorporation prevail.

Harvard Medical School.—A gift of $250,000 from Mrs. Collis P. Huntington, announced March 13th, more than completes the sum of $765,000 required to secure the $1,000,000 offered by John D. Rockefeller of New York for the enlargement and endowment of the Harvard Medical School. Mrs. Huntington's subscription is specifically for the erection of a building in memory of her late husband, to be called the "Collis P. Huntington Laboratory of Pathology and Bacteriology." With Mr. Rockefeller's gift and the pledge made by J. P. Morgan last June to give three buildings at a cost exceeding $1,000,000, an aggregate of $2,821,225 will be available for the use of the Medical School.

National Health Board.—The bill to change the name and increase the efficiency of the United States Marine Hospital Service, favorably commented on previously in the editorial columns of the Medical News, was favorably reported to the Senate by the Committee on Public Health and National Quarantine, March 15th. It changes the name to the United States Health Service. The bill provides for creating an Advisory Board for conducting investigations by the Hygienic Laboratory, and provides also for the creation of a National Board of Health, to consist of one delegate from each State or Territorial Board of Health, to meet for conference when upon the request of five of these boards the interests of the public health can be promoted thereby. The uniformity of registration of mortality, morbidity and vital statistics is provided for by authorizing the Surgeon-General of the United States Health Service after conference with the State boards to prescribe forms for their collection and compilation. In the time of threatened or actual war, when the commissioned officers of the United States Health Service are brought into official relations with the medical officers of the Army or Navy, they are to have rank with and after those of similar rank in those services.

Obituary.—Dr. J. Baxter Upham died last week in New York, at his home, after an attack of indigestion. He had been ill for two days. He was eighty-two years old and was born in Claremont, N. H. He was graduated from Dartmouth College in 1842 and from the Harvard Medical School in 1848, practised medicine in Boston until the outbreak of the Civil War, and then enlisted to serve through the war as a surgeon-major under Gen. Burnside. After the war he resumed practice in Boston. In 1880 he came to New York and formed a copartnership with Austin Corbin in the Corbin Banking Company. Two years later he retired on account of ill health. He was a delegate to the International Medical Congress.

New Buildings for Medical School.—The Columbian University of Washington, D. C., has just completed plans and let contracts for the erection of a new hospital building and a new medical and dental school on H Street, N. W., between 13th and 14th Streets. The buildings will be Colonial in style, the hospital having a frontage of 60 feet to the south; the medical school building, 50x144 feet, will be five stories high. Large new laboratories thoroughly equipped for modern work and well-lighted lecture- and reading-rooms will afford excellent facilities for medical and dental students.

CORRESPONDENCE.

CURABILITY OF TUBERCULOSIS.

To the Editor of the Medical News:

Dear Sir:—Major D. M. Appel, U.S.A., the Commanding Officer of the Government Sanatorium for Tuberculosis at Fort Bayard, New Mexico, has been widely quoted in the lay press as saying, in an interview with a newspaper representative at Albuquerque, New Mexico, that "tuberculosis is curable in every stage." If true, this statement is fraught with the greatest interest to the human race; if not, the error should be at once corrected. If Major Appel has been rightly quoted, and the words "you may quote me," which precede his statement, would indicate that he has, then, unquestionably, he spoke in good faith. It is far from my purpose to attribute to Major Appel an intention to mislead or equivocate, but that his utterance is misleading, I am thoroughly convinced; and that it requires explanation and qualification, I am also convinced. No one realizes more keenly than I the efficacy of the climate of New Mexico in tuberculosis, and I am sure that nothing but the truth is necessary to substantiate New Mexico's claims. Let us suppose that a patient, in a late stage of tuberculosis, lying in his bed in St. Luke's Hospital in New York, has his attention directed to the issue of the *New York Herald* in which one whose position lends authority to his words gives utterance to the statement that "tuberculosis is curable in every stage." Such a one receives renewed hope. He is possessed by the idea that he may, after all, recover; and, if it can in any way be managed, he will make his way to New Mexico, seeking the life-giving conditions which this statement justifies him in expecting to find there. Will he be disappointed? My whole experience says that he will; and that, in the majority of cases, such patients will die far from home and friends. It is in just such cases as this that such a statement may do incalculable harm.

We, most of us, remember the enormous influx of tuberculous invalids into Berlin which followed the premature announcement of Koch's tuberculin. They went as to a Mecca, where human ills and pains were sure to be assuaged. Were they disappointed? We all know the answer to that question. Is there to be a like immigration of incurable sufferers into New Mexico? I trust not. And, in a measure, to prevent such an occurrence, I feel it my duty to urge that Major Appel's statement be not taken literally, and to add my own interpretation of what I believe to be the facts. If called upon for an opinion as to the curability of tuberculosis in our climate, I should not hesitate to say that here, by rigid adherence to the phthisiotherapeutic principles of Brehmer, results can be obtained which are unsurpassed and which prove a revelation to the phthisiotherapist who works in an unfavorable climatic environment. And, further, that more patients in the so-called advanced stages of consumption recover here, at least relative health, than anywhere else; but the statement that tuberculosis is curable in every stage is not substantiated by facts. From this, it should not be implied that a patient in an advanced stage is necessarily incurable. I have before me the first annual report, made by Major Appel of the Government Sanatorium at Fort Bayard, in which, under the head of "Cases Presenting Permanent Febrility with Tubercle Bacilli in the Sputum," he says: "Of the forty-eight patients in this class, twenty-four, or 50 per cent., died; twenty, or 42 per cent., were discharged unimproved; and four, or 8 per cent., improved in general condition. None was cured or discharged convalescent." Of this same class, fourteen patients were under treatment at the time this report was written. Their conditions at that time, according to the report, were as follows: "Nine, or 64 per cent., are unimproved; four, or 28 per cent., improved in general condition; and one is convalescent." Under the head of conclusions regarding discharged cases of this type, is the following: "With a death-record of 50 per cent. and a hopeless prognosis in the remainder, the futility of climatic treatment for this class is unquestionable."

The foregoing quotations and the statement "that tuberculosis is curable in every stage" cannot be reconciled, and it would appear that the recent, widely-quoted statement of Major Appel is misleading and calculated to do great harm.

E. S. Bullock,
Medical Director,
St. Joseph's Sanatorium.

Silver City, New Mexico, March 8, 1902.

TRANSACTIONS OF FOREIGN SOCIETIES.

British.

OBESITY—OLD STANDING PARALYSIS—DYSENTERY—MAMMARY CANCER—PAPILLOMA OF THE VAGINA—VACCINIA.

The month of January saw the British Societies very active. Among the many valuable discussions held the following are worthy of attention.

T. Lauder Brunton opened a discussion on the nature and treatment of obesity, which he defined as a condition in which the fat is very much greater than normal and sufficient in quantity to become inconvenient to the patient. His definition was made accurate and illustrated by the following facts. The average height of the English is five feet eight inches, and weight one hundred and fifty-four pounds, remaining constant until about the fortieth year, when a gradual increase in weight begins. According to Van Noorden this increase might reach 15 per cent. and still remain within what should be called the normal limit. If it reached 30 per cent. the person became "stout," between 30 and 35 per cent. "too stout," from 35 to 50 per cent. "moderately obese," above 50 per cent. "very obese." The accumulation of fat occurred usually in the subcutaneous tissue, omentum, around the heart and kidneys, consisted chiefly of mixtures of different proportions of glycerin, united with fatty acids. These mixtures vary in different animals, but each animal keeps its own fat nearly at a constant standard, although it might feed on other animals having a different kind of fat. This not altogether the case. As an old nurse of S. Weir Mitchell has remarked, some fats are fast, some fats are fleeting, but cod-liver oil fat is soon wasted. This has been proved scientifically, for in animals fed on rape-seed oil, this oil can be detected unaltered in the tissues. The accumulation of fat in man depends first on how much fat or fat-forming food is taken into the body, and second upon how much food is consumed in the ordinary processes of life. Either

of these causes may act separately or both together. Fat is, however, formed from different kinds of food, even if fat itself is not contained in them, such as the albuminoids, and carbohydrates. The body is able to make food with difficulty from albuminoid materials, such as lean meat, but with considerable ease from the carbohydrates, like sugar and starch. Therefore the tendency to lay on fat is determined by the nature of the food. The tendency to the accumulation of fat both in men and animals after the removal of the testes and ovaries is well known. Loewy and Richter found that in dogs the administration of extract of the ovaries has no effect if these organs are in the body of the animal, but increases oxidation in animals from which the ovaries or the testicles have been removed. It is usual to distinguish two forms of obesity, the plethoric and the anemic. Instances are known in which plethoric obesity was benefited by violent exercise, which may or may not be accompanied by a peculiar diminution of the mental activity. Anemic obesity is most frequent in women. Diseases which lessen activity tend to cause obesity, especially chronic nephritis on account of the languor which it produces. With regard to the treatment of obesity, as the cause of the condition either in severe or slight form consists in taking in more fat-making food than the body can burn off, the treatment naturally consists in limiting food, both in quantity and in quality, and in increasing the combustion by accelerating the circulation. Active muscular exercise is certainly the best means of carrying out the latter point, but in severe cases the patients cannot take muscular exercise. In these massage is exceedingly valuable, but is alone not sufficient and must precede rather than supplant active exercise. The amount of food should be lessened in general by insisting that solids and liquids should be taken at different times. Many are apt to wash down food, especially farinaceous food, without much chewing. If this starchy food were made dry, like toast, rusk, and biscuit, the quantity taken without the aid of fluid would be much less. Digestion in the stomach has less tendency to form fat than when the digestive process is carried on in the intestine. This gives a good index of the kind of food most suited to these patients. It is necessary to secure active elimination of the products of combustion. Thyroid extract increases tissue change and may be used to decrease obesity. But diet and exercise are safer and in the long run more reliable.

J. P. Stewart and Mr. Tubby, at the Clinical Society of London, January 24, 1902, showed a case illustrating a new method of treating old-standing paralysis of the upper root of the brachial plexus. The patient was a man fifty-seven years old, who had fallen on his shoulder and head two years ago, with resulting unconsciousness for an hour afterward and paralysis of the left arm upon recovery. After treatment at various hospitals without benefit he was admitted to the Westminster Hospital under the care of W. Murrell, showing marked paralysis and atrophy of the left shoulder and upper arm, with total loss of electrical excitability in the deltoid, infraspinatus, biceps, brachialis anticus, and supinator longus muscles, with consequent inability to adduct the arm or to flex the elbow. There was loss of sensation along the outer side of the upper arm and forearm, which subsequently disappeared. These symptoms pointed to a paralysis of the upper root of the brachial plexus of the Erb-Duchenne type. Twenty months after the accident Mr. Tubby transferred part of the triceps and fixed it into the biceps, with the object of restoring the power of flexion at the elbow, and a month later an attempt was made to restore power to the deltoid. Since the operation the transplanted portions of the muscles have been assiduously massaged, and the faradic current had been applied. There had been great improvement in the movements and in the utility of the limbs. The patient could flex the elbow fairly well and during this act the transplanted part of the triceps could be felt in front of the elbow and both faradic and galvanic excitability had returned. He had not yet recovered power to adduct the arm, but the transplanted part of the pectoralis major could also be felt to harden. At first there was a total loss of excitability both to induced and galvanic currents, but three months after the operation, the galvanic excitability returned and six months after, faradic reaction had become apparent.

Dr. Washbourne read a paper at the Epidemiological Society January 17, 1902, in which O. Richards had taken a share in authorship. It dealt with South African dysentery and its relation to that in asylums. Three types of the disease were described, alike marked by bloody and mucous stools, fever, tenesmus, and abdominal pain in different degrees. The normal type, with its febrile stage, lasted a week with the temperature between 101° in the morning and 104° F. in the evening, with a thick white fur on the tongue, and with the symptoms subsiding in a week or becoming chronic, unless death occurred in the first week from the fever itself, or subsequently from the perforation, peritonitis, or exhaustion. The second type comprised mild non-febrile cases soon recovering, and the third was distinguished by the pyrexia which continued for three or four weeks, with perhaps an entire absence of blood and mucus, the bowels being either loose or constipated. The cases were often taken for enteric fever, but were doubtless due, like the typhoid form of scarlet fever, to secondary septic invasion. The mortality in South Africa had been low. Only about 1.86 per cent. had died. Liver abscess was rare. In one case the base was full of streptococci and bacilli, thus differing from the usual tropical form. The cecum and rectum were most affected, the lesions being thickening of the walls with hemorrhages and ulceration. Perforation was the most frequent cause of death. No amebæ had been found in the contents of the intestine or in the abscesses themselves.

R. J. M. Buchanan, at the Liverpool Medical Institution, January 23, 1902, referred to the subject of mammary cancer in the light of heredity on the one hand and of the parasitic theory on the other. In view of the transmission of minute details of conformation and disposition from parents to children in heredity, he thought it a proper consideration that the peculiarities of cell reproduction might also be transmitted, and that the characteristics of cell structure as seen in cancer growths might in some way be associated with stages in karyokinesis. He showed a specimen of *tradescantia virginica,* showing the various stages of cell division and drew attention to the fact that nuclei of many cells at a similar stage presented structures closely resembling cancer bodies. He referred to the variations of the centrosome in cell division and to the possibility that cancer bodies might be of centrosomic origin and expressive of an exaggerated or abnormal condition of the centrosome. The question of heredity transmission he considered applicable both to the developmental and parasitic theories. In the former as reproducing special peculiarities in the life histories of cells, in the latter as reproducing a light susceptibility in a high degree of parasitic invasion. Referring to the parasitic theory in relation to the etiology of cancer, he stated that his endeavors to cultivate the so-called parasite proved unsuccessful, and that he was not fully satisfied with the results of other observers in view of the grave possibilities of contamination and the lack of evidence that inoculations of organisms isolated from

cancer have reproduced this disease. This might be due to differences in experimental technic, and, apart from the purely experimental method to isolate and reproduce cancer by inoculation, he thought that some consideration should be given to the circumstantial evidence in favor of the parasitic theory as offered by records of geographical distribution, the existence of cancer houses and conditions of environment, associated with the occurrence of the disease. Relating to this, he did not accept the statement of Banks that a diet of flesh predisposes to cancer, but rather that a diet of raw vegetables tended to it. He felt that the parasite most probably is introduced into the body through the medium of some lower form of animal life which is in constant association with it and especially such vegetables as are used for food. On inquiry, in certain cases of cancer he had noted that the houses in which the affected individuals resided were infested with snails to a remarkable degree and in many cases the victims had been addicted to indulgence in salad as an article of diet.

Dr. Walter, at the North of England Obstetrical and Gynecological Society on January 17, 1902, reported a case of recurrence of papilloma of the vagina in an unmarried patient, thirty-seven years old, admitted to St. Mary's Hospital, Manchester, in August, 1899, complaining of bleeding from the vagina between her periods, which had continued off and on for several months back. Her general condition was good. The uterus and other pelvic organs were healthy. Inside of the vagina on the posterior wall was a small papilloma which bled readily. This was scraped away and the cautery applied freely to the base. On microscopical examination of the scrapings, the appearance of a simple papilloma with no sign of malignancy was shown. In November, 1898, the patient reentered the hospital as the papilloma had recurred. The cautery was again applied. The following year on two occasions similar treatment was necessary. In 1900 the patient was readmitted in June and in December. The patches were larger in size than formerly, but were still quite superficial and were free from any deep-seated attachment. The cautery was applied to the affected surface. Last year in March, July, October, and December, the patches had returned and were spreading upward on the posterior and left wall. In December it was found that infiltration into the perivaginal tissue on the posterior and left side had occurred since her previous visit. As the vagina was extremely narrow, the perineum was divided and the part was exposed to view. A patch of mucous membrane of the size of a shilling with a raised and granulating surface, together with a small growth nearly as large as a nut, was removed and the vagina was packed with gauze. The microscopical appearance of this growth was a fibrous and elastic tissue basement, containing a considerable number of cell nests.

E. J. McWeeney, at the Royal Academy of Medicine in Ireland, before the Section on Pathology, on January 10, 1902, read a paper on the cause of vaccinia. He said that since the work of Von Thieme, Ceely, Voigt, and Fisher, there could be no doubt that vaccinia was merely smallpox modified by passage through the calf. The microscopical etiology of both diseases must therefore be the same. Since the commencement of the bacteriological epic repeated and unsuccessful endeavors had been made to establish a bacterial etiology of these maladies. Among the most recent of these attempts might be cited those of Klein, Copeman, Kent, Nakanishi, Czaplewski, and Vanselow. Mann had demonstrated that in sections of vaccine, tissue appearances closely resembling micro-organisms, but really consisting of granular or rod-like precipitates of stain, might be produced in the process of carrying out Gram's method. The bacillus of Nakms was at once recognizable by any one familiar with the microbes of the calf's skin, such as the xerosis bacillus. It closely resembles that of diphtheria, but is harmless. Similarly the micrococcus quadrigeminous of the last-named observers had been recently admitted by themselves to be devoid of all etiologicial relation to the vaccine process. The attempts to prove that variola and vaccinia were due to a parasitic protozon were begun in 1886 by Vander Loeff, continued by L. Pfeiffer of Weimar, and still further developed by Guarnieri of Piesa, and by Pfeiffer's pupil, Wasielewsky. To Guarnieri belongs the credit of having selected as the field of observation the rabbit's cornea, a transparent, non-vascular structure, in which the histiological events could be observed uncomplicated by the vascular and exudative phenomenon of inflammation. He saw in epithelial cells of the inoculated cornea rounded bodies varying in size from that of a minute coccus to about one-third of the epithelial nucleus. They lay in the protoplasm, often close to and even uniting the nucleus. Ameboid movements were observable on the worm stage and E. Pfeiffer saw bodies lying *between* the epithelial cells an hour after vaccination and *within* them a few hours later. Several observers, such as Ferroni, Massari, Salmon, and others, had endeavored to explain these bodies as resulting from irritation of the non-specific kind, but Huckel while not admitting their parasitic nature had been led to infer that they were the result of some alteration of the cell produced by the parasite or its toxin. E. Pfeiffer had shown that lymph that had lost its activity through filtration or otherwise was incapable of producing these bodies in the cornea. Wasielewsky had propagated the vaccine virus on the rabbit's cornea for forty-three generations, and used the corneal epithelium scraped off the forty-third consecutive rabbit for vaccinating children and had produced a large percentage of typical vaccinations. The only feature presented by such virulent epithelium and not presented under any circumstances by normal or otherwise rooted epithelium was the presence of these bodies described by Guarnieri. For this reason it was difficult to escape the conclusion that the bodies were the carriers of the infection. Beyond the seeming existence of a nucleus, the most careful examination had failed to reveal much structure in the bodies as are found in the affected epithelium and as to their reproduction and developmental cycle little or nothing is known. The paper closes by showing the several stages in the evolution of the vaccine vessel, illustrated by lantern slides and actual preparations; the author also exhibited slides and sections of the inoculated rabbit's cornea, in which every cell was seen to harbor one or more of these bodies.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 20, 1902.

The Second Vice-President, Charles L. Dana, M.D., in the Chair.

The scientific business of the evening consisted of a Symposium on Vaccination.

Health Department and Smallpox.—Dr. Alonzo Blauvelt said that the announcement of a smallpox case comes to the New York Board of Health either from a physician or a citizen, by telephone or by mail, or through anonymous letters, reporting supposed cases, which are always investigated, but very rarely prove to have basis in fact. When the message is received the sergeant of the police station in the district in which

the patient resides is asked to send a policeman to watch the premises and to accompany the diagnostician of the Board of Health when he arrives. If the diagnostician finds the patient suffering from smallpox, he visits all the other rooms of the house, vaccinating every one besides looking for other cases. Careful inquiries are made as to all those who have been in contact with the patient, and as far as possible they are vaccinated. The diagnostician takes note of all articles in the room or in use by the sick person and these are fumigated by the Board of Health which sends a wagon for them; after twenty-four hours they are returned in another wagon. A week later inquiries are made as to the condition of the persons vaccinated and in cases in which the vaccine material has not successfully taken, revaccination is offered. All school-children living in the house are kept from school for three weeks, as are also teachers. School-books in the house are destroyed if the superintendent of the school makes a request to that effect. Vaccination is offered to all in the immediate neighborhood of the patient and these cases are further investigated in order to be sure that the virus has had its protective effect. A patient suffering from smallpox in any stage is at once removed by ambulance or coupé to Riverside Hospital on North Brother Island. After use for the transfer of a case of smallpox the ambulance or coupé is thoroughly fumigated by formaldehyde gas in a room specially arranged for this purpose. No exceptions are made to this rule of removal, no matter what the circumstances of the patient.

Dry Points versus Glycerinated Virus.—Dr. M. J. Rosenau, Director of the Hygienic Laboratory of the Marine Hospital Service at Washington, read a paper on the bacteriology of dry points and glycerinated virus. He said that bovine virus has the advantage of not containing human diseases, hence its general use; bovine virus may, however, carry pus cocci and other undesirable micro-organisms, and the greatest care is needed to protect human beings against this injurious inoculation. In 1891 Dr. Monckton Copeland of London showed that glycerin inhibited the growth of all micro-organisms associated with vaccine virus and destroyed most of them. Glycerin is not an antiseptic, but it slowly kills by dehydration. Diluted glycerin may be a culture medium for micro-organisms. Glycerin also eventually destroys the power of vaccine virus, but this occurs later than the death of the micro-organisms hence the special effect of the use of glycerin. Glycerin should be added to virus from four to six weeks before it is used. Dr. Rosenau made his observations on dry points and glycerinated virus bought in the open market and kept under proper conditions of air and light. Forty-one dry points showed an average of over 4,000 microbes on each point. Forty-one samples of glycerinated virus showed an average of 2,800 microbes in each sample. This is entirely too many, considering the normal bactercidal efficiency of glycerin. Some of the micro-organisms found in the glycerinated virus were the ordinary pus cocoi and the mircrobes of hemorrhagic septicemia. While all these developed in bouillon, they were found to be without virulence for the ordinary laboratory animals and apparently had lost some of their normal activity. The presence of so many micro-organisms in glycerinated virus seems to show that manufacturers put on the market green virus —that is, vaccine virus mixed with glycerin only a few days before delivery for use. When glycerinated virus was kept for five or six weeks at the laboratory the number of micro-organisms fell in most cases to less than 200 per sample. This seems to be an absolute demonstration of the necessity for longer contact of the virus with the glycerin.

Dangers of Glycerinated Virus.—One of the specimens of glycerinated virus examined contained molds and other micro-organisms, indicating stable contamination, which points out the danger that may occur from over confidence in the efficiency of glycerin in destroying micro-organisms. The strictest precautions should be taken to prevent the contamination of vaccine material; manufacturers must not depend on the destructive power of the glycerin and practise economy by lessening their antiseptic precautions. The glycerinated virus of one manufacturer contained more micro-organisms than the dry points manufactured by the same firm. Dry points, when kept for some time also have fewer micro-organisms, the drying process causing bacteria to lose their vitality. One reason for difference in the number of micro-organisms in certain cases is that the tubes containing the glycerinated virus vary greatly in size. Some of them contain ten times as much as others. The quality of the micro-organisms, and especially the frequent presence of pus cocci and of microbes of the hemorrhagic septicemia variety, evidentally show the need for proper control. The enforcement of government inspection with power to prevent the sale of improper material seems to be the desideratum.

Clinical Comparison.—Dr. F. S. Fielder read a paper on the value of the dry points compared with that of glycerinated virus in the actual practice of vaccination. Dr. Fielder made a series of clinical tests in connections with the laboratories of the Board of Health of New York City. From twenty-one calves dry points and glycerinated virus were prepared which were tested on primary vaccination cases. Ten children were vaccinated in three places, there being fifteen insertions each of dry point and the glycerinated vaccine material. Each child was inspected six or seven days after vaccination in order to determine whether vaccination had taken or not, and three or four days later to determine the constitutional reaction, rashes and so forth, that might occur. The glycerinated virus was successful in 95 per cent. of the insertions; the dry points in only about half the cases. The quality of the resulting vesicles was very much better with glycerinated virus than with the dry point. The failure of the latter seems to be that not so much of the base of the vaccine vesicle in which the vaccine bearing bodies reside is obtained on the surface of the dry point as in the glycerin emulsion. It is the presence of these apparently protozoic bodies that makes the vaccine material efficient, and anything that secures a large number of them for vaccination purposes is sure to produce more uniform success.

Rashes and other Accessories.—There was somewhat more rash noted in cases vaccinated with the dry points than in those in which the glycerinated virus was used. As by the conditions of the experimental observation, however, the glycerinated virus employed was green—that is, inoculated within a few days of its preparation and without waiting the customary five or six weeks for the glycerin to effect its purpose of destroying attendant micro-organisms—it is not surprising that some rashes were noted with it. One rash resembled very much that of varicella, but as it occured four days after vaccination it was thought to be due to the vaccine virus. Such cases of varicella-like rash have been seen before; in this case, however, another child in the family developed a varicella-like rash two weeks later, though it had been vaccinated the previous year and the lesions ran the typical course of true varicella.

Tetanus and Vaccine Virus.—Dr. John H. Huddleston read a paper on the possible relations between tetanus and vaccine virus. Tetanus as a sequel of vaccination is rare and it has occurred indiscriminately

after the use of dry points and glycerinated virus. The most careful investigation of a large series of cases shows that no case of tetanus ever developed at a time when according to the usual incubation period of tetanus, it would seem probable that both tetanus and vaccinia could be inoculated together. It is well known that tetanus bacilli occur in horse manure in considerable quantities. This is considered to be the principal source of tetanus bacilli in large cities.

Cow-Manure and Tetanus.—It is not known by any definate set of experiments as yet published whether or not tetanus bacilli occur in the stools of cattle. Dr. Huddleston, in connection with his Board of Health work in New York, instituted a series of observations to determine the occurrence and non-occurrence of bacilli in calf-manure. Cultures were made from 25 samples of manure passed shortly after calves were admitted to the vaccine laboratory; these calves had been fed on hay on which is known that the tetanus bacillus occurs thus finding its way into the intestines of animals. Six of the twenty-five samples gave cultures of bacilli suspiciously resembling tetanus bacilli. Two of the micro-organisms thus found withstood a temperature of 95° F. for an hour. When injected into animals, these bacilli produced tetanic spasm, and two days after the animals died. With the idea of determining whether calves are susceptible to tetanus or not, tetanus bacilli were inoculated with cultures of the bacillus. In small amounts they failed to produce any reaction. Used in larger amounts and introduced by means of scarification they did not cause symptoms. Tetanus bacilli smeared over the teats of the animals from which vaccine matter were to be obtained penetrated to the bases of the vesicles and all of the vesicles gave serum from which cultures of spore-bearing anaerobic organisms could be obtained. To the toxin of the tetanus, calves proved to be extremely insusceptible; after large quantities had been used without success, all the toxin in the laboratory was introduced into one calf, nearly a thousand c.c., and only then was there a fatal result.

Sealed Tubes and Tetanus Bacilli.—It has been said that the sale of vaccine virus in sealed tubes really favors the growth of tetanus bacilli, if any should by chance be present in the material; these sealed tubes are supposed to provide a favorable anaerobic location for the growth of the bacillus. In order to test this question, Dr. Huddleston inoculated bouillon and water with tetanus bacilli and then enclosed the contaminated material in sealed tubes. The tetanus bacilli multiplied very noticeably. When glycerin was added to the bouillon and water, however, there was no growth of the tetanus bacilli, though the sealed tubes were kept at the most favorable temperature for their growth for many days.

Vaccine Matter and Tetanus.—Animals inoculated in the ordinary way with vaccine material known to be contaminated by tetanus bacilli did not contract the disease. Very susceptible animals as far as regards tetanus were used for these experiments and it is evident that tetanus is not easily transmitted by the scarification method, as might be expected from the well-known anaerobic character of the micro-organism. It refuses to grow in the presence of oxygen and superficial wounds are never a source of tetanus. Tetanus occurs by special preference after deep wounds, because then the bacillus becomes buried in the tissues far away from the free oxygen of the air. It is not surprising, then, that the Royal Commission appointed in England to investigate this subject reported only one case of post-vaccinal tetanus, even that not due to coinfection.

Exaggerated Claims for Glycerinated Virus.—Dr. Foster said that he is an opponent of the use of glycerin in the preparation of vaccine virus. Exaggerated claims for the effect of glycerin on vaccine material in the destruction of intruding micro-organisms have been made without sufficient reason. Dr. Foster considers that Dr. Rosenau has approached the subject from a different and more rational standpoint from that usually assumed in the literature of this subject. He is accustomed to hear it said that in glycerinated virus there can be no possible danger. Dr. Rosenau has shown that any danger that exists is quite as real with glycerinated virus as with dry points unless proper precautions are taken. The use of glycerin has been put forward as an alleged safeguard, and has thus led to the neglect of many other needed precautions. Many of the glycerin preparations of vaccine virus on the market are, as has been shown by Dr. Rosenau, not what they are represented to be. Undoubtedly some of the bad results recently reported in vaccination cases have been due to the neglect of proper precautions in the preparation of this glycerinated virus.

Use of Dry Points.—Dr. Foster, who has had much experience in the preparation of dry points and in the use of vaccine material according to this method, says that in order to keep properly dry points should be subjected to artificial desiccation; drying of the most thorough kind at an ordinary temperature is not entirely efficient. When properly prepared, dry points present many features of excellence and are not superseded by glycerinated virus. Their satisfactory employment for long years by the profession, under all sorts of circumstances, makes an excellent practical proof of their value.

Japanese Experience with Vaccine.—Dr. Kinyoun, Medical Inspector of Foreign Laboratories for the United States Marine Hospital Service, said that Kitasato, who is in charge of the Japanese government laboratories for the manufacture of vaccine virus, after a series of the most careful observations, has decided that glycerinated vaccine material should be exclusively employed. Dr. Kinyoun had seen in Japan a series of thirty-eight successful primary vaccinations done upon children. Sixty out of three hundred and sixty adults had been successfully vaccinated in a secondary vaccination. The comparatively few successful results are due to the fact that the Japanese as a nation are universally vaccinated in childhood and at intervals thereafter. The confidence of the Japanese in the protective power of their vaccination is such that no restraint is practised with regard to smallpox; there is no quarantine, and except in remote country districts, practically the whole nation is immune to smallpox from repeated vaccinations. Japan furnishes at the present time the best possible proof of the value of vaccination against smallpox.

Strength of Vaccine Material.—Dr. Kinyoun said that the first part of the lymph that comes from the vaccine vesicle contains more vaccine material than the subsequent fluid contains. Down in the pulp at the base of the vesicle the vaccine particles are contained and are gradually washed away by the issue of serum. Points made, then, from the later portion of the contents of the vesicle are apt not to be so successful in their effects. Dr. Kinyoun was associated with Dr. Monckton Copeland at the time of his researches on the use of glycerin, and his experience convines him that glycerinated virus properly prepared is greatly superior to the dry point.

Manila Sore Arms.—The experience with vaccination at Manila has not been very satisfactory. For some reason the virus used there produces untoward results and extremely sore arms. The glycerinated virus does not seem to be free from micro-organisms that produce serious infective processes. One

of the difficulties has been that owing to the temperature, the vaccine virus is used immediately, and so the glycerin has not its proper opportunity to destroy or greatly lessen the vitality of undesirable micro-organisms. In Japan the best results are obtained by the intimate division of the vaccine pulp, so that only minute portions of tissue are mixed with the glycerin; this enables the glycerin to reach every part of the vaccine material and helps it to produce its antiseptic effect much sooner than would otherwise be the case. The vaccine virus thus prepared does not last as long as other glycerinated virus, but its additional advantages more than compensate for this. The virus issued in Japan is supposed to be effective only for sixty days.

Filtered Lymph.—Dr. Jacobi asked if Dr. Huddleston had stated that filtered lymph was incapable of producing true vaccination. He said that in the old days physicians obtained their vaccine material by watching their cases very carefully and obtaining serum from vesicles when they were absolutely clear and as yet unclouded; this perfectly clear serum was well recognized to be the most effective vaccine material and to contain no undesirable qualities. This serum was collected on a series of ivory points or in a goose quill, the most important consideration being to avoid the pus stage of the vaccine vesicle because at this time the virus had deteriorated. This had also been the custom in the villages of Germany in which Dr. Jacobi had lived and there is no doubt of the efficiency of the vaccine performed with this perfectly clear material.

Filtered Vaccinal Serum.—Dr. Huddleston said that the serum of vaccine vesicles after filtration is absolutely inefficient. The reason for this is that the vaccine virus is contained on minute particles, which are, however, not small enough to pass through an ordinary filter. The dry particles filtered out of the serum may be used with success for vaccination purposes, but not the filtered serum. The clear serum found in vaccine vesicles contains, however, a certain number of particles that have been washed out of the pulp beneath, and these are capable of producing efficient vaccination.

Life of Vaccine Material.—While ordinary glycerinated vaccine virus is not supposed to last more than two or three months, observations by the New York Board of Health show that the life of certain specimens is as long as thirty months after its original issue. Glycerin does not produce its action as an antiseptic merely by its drying power; even when diluted to 50 per cent. glycerin is still active in preserving vaccine virus and in destroying accessory micro-organisms. It is not its special affinity for water, but probably some chemical quality of the glycerin that gives it its bactericidal action.

Active Vaccine Bodies.—Dr. Rosenau, in closing the discussion, said that a series of observations made recently show that the bodies which produce the protective effect in vaccination have an especial affinity for epithelial tissue. These bodies have been grown upon the corneæ of animals and then transferred to other parts of other animals for vaccination purposes with success. In one set of observations the vaccine material was transferred forty-six times from cornea to cornea and still had its power of producing a typical vaccine vesicle. Some manufacturers use glycerinated virus not contained in sealed tubes, but on the ends of ivory or bone points. This method of manufacture does not seem to have any very special advantages, though it is claimed that it inhibits the growth of anaerobic micro-organisms better than when sealed in capillary tubes. He said that much remains as yet to be done in pointing out the special dangers of vaccine material manufacfacture and that a large field lies open for the special worker in this line.

SOCIETY OF DERMATOLOGY AND GENITO-URINARY SURGERY.

Stated Meeting, Held February 14, 1902.

The President, R. H. Greene, M.D., in the Chair.

A Case for Diagnosis.—Dr. H. H. Whitehouse presented the following case for diagnosis. The patient, a man twenty-five years old, presented an eruption of eight months' duration. He had had a similar eruption five years ago but, at that time, it was confined to the lower legs. He was treated by a noted dermatologist in Vienna, first with chrysarobin locally, and later, according to the patient, by injections twice a week with a "quick-silver" preparation. The eruption disappeared within five weeks. The family history is negative. He has had gonorrhea and considerable sore throat and headache, but nothing very definite. He denies chancre. The eruption is extensively distributed over both legs, thighs and buttocks, with patches upon the arms and forearms; there are but few lesions upon the trunk except over the sacrum where the patches are numerous. Scalp, face, palms and soles are free and there are no lesions in the mouth. He complains of intense itching and burning symptoms which were present also in a marked degree during the first attack five years ago. The eruption consists of circinate spots made up of papules grouped into horseshoe or crescentic patches, forming gyrate figures. There is a marked solidity to the papules, the color of which is a dull red. Some papules are devoid of scales, while others have adherent dry silvery scales resembling very closely those of psoriasis. Some patches are clearing in the center and pigment spots are present at the site of former lesions. There is a well marked postcervical and inguinal adenopathy.

Dr. James C. Johnson thought that two attacks, exactly of the same type, occurring five years apart, was sufficient to exclude syphilis. In old cases psoriasis, typical in its distribution, never entirely disappears; the fact that the eruption cleared up under mercurial treatment is not sufficient reason to exclude psoriasis.

Dr. Lapowski did not believe that it was syphilis, but that it was a case of psoriasis and seborrhea combined.

Dr. T. C. Lusk said many, for instance, Walker, claimed that psoriasis was but a form of seborrheic eczema.

Syphilitic Growth in the Perineum.—Dr. H. H. Morton presented this specimen which was taken from a patient who gave the following history: A. J., colored, about forty years old. Has had gonorrhea several times, his last attack occurring one year ago. He now appears entirely well. In October, 1900, he had a sore on his penis which lasted until March, 1901. This was followed by enlarged glands and sores in his mouth, which lasted for three or four months. His present attack began two months ago, with a swelling in the perineum which grew slowly larger and caused difficulty in urination. On December 30, 1901, an operation was performed. An external urethrotomy for a supposed abscess of Cowper's gland, or extravasation of urine was performed. The skin of the perineum was incised and a hard tumor lying over the urethra was exposed. This tumor lay nearly in the median line, but slightly to the left side. The tumor was split in half and the urethra exposed. There was a considerable amount of peri-urethral infiltration and thickening. A stricture of large caliber was divided. The tumor was dissected out with curved scissors and a large catheter introduced into the bladder for drainage. The wound was stitched, but left open. February 15th he had a beginning attack of acute articular rheumatism. Perineal wound had nearly closed.

Dr. Murray, the pathologist of Hoagland Laboratory, made the following report: "The microscopical examination of tumor removed from near urethra in patient at King's Hospital shows the mass to be composed of muscular, fibrous and areolar tissue, the whole being invaded by an enormous number of small round cells. There is, also, a very extensive obliterating endarteritis and endophlebitis with perivascular small round-cell infiltration. A few cross-sections of ducts, apparently from mucous glands, are seen in parts of the mass. The growth has all the appearance of being syphilitic."

Dr. Cabot thought that it was an unique case and said it would have been interesting to have learned what the effect of treatment might have been upon a growth of that kind. He thought the growth came very soon after the primary lesion for a gumma.

Dr. Lusk said that it looked more like a keloid growth than a gummatous growth. The colored race were very prone to develop keloid and any kind of irritation seems to be followed by such a formation, especially in syphilitic patients.

Dr. Johnson said that the pathologist was very careful not to commit himself when he stated in his report "the growth has all the appearance of being syphilitic." He made his diagnosis chiefly upon the condition of the blood-vessels in that he stated that there was an extensive obliterating endarteritis and endophlebitis. He knew of no way by which a diagnosis could be made with the microscope between syphiloma and tuberculosis of the skin except by finding the tubercle bacilli. He thought the pathologist was perfectly right in stating that the condition was the result of previous injury and was syphilitic in character.

Hypertrophy of the Prostate.—Dr. H. H. Morton presented this specimen. The patient, F. B., a Finlander, by occupation a tailor, aged sixty-two years, had never been ill before his present sickness. His family history is negative. He has had a little trouble in passing his urine for one year past. He went to a physician to have some sounds passed and this the doctor was unable to do, but he did make a false passage in the posterior portion of the prostate; immediately after this accident the patient came to the hospital, being admitted on December 5, 1901. He was suffering from retention of urine and great distention of the bladder. It was impossible to pass any instrument into the bladder as all instruments went into the false passage. External urethrotomy without a guide was done. The finger introduced into the perineal opening showed an enormous enlargement of lateral lobes of the prostate and the entire prostate formed a ring around the vesical orifice. The bladder was drained through a large catheter for three weeks, but complete retention occurred as soon as the catheter was removed and so it was put back and left until January 10th when prostatectomy by the Alexander method was performed. The bladder was opened suprapubically and the perineal wound was used for shelling out the prostate from its capsule. There was no hemorrhage; the bladder was drained through the suprapubic wound and a perineal tube. January 13th: Bladder has been draining thoroughly through the tubes. Urine, from 40 to 60 ounces in twenty-four hours. Patient has shown no signs of shock, feels well, and is free from pain. Temperature ranges from 99 to 101° F. Patient has had urotropin; water to drink every two hours, the bladder has been washed out, and he has been turned from side to side every hour. The wounds look healthy. To-day he had a chill and rise of temperature to 104° F. January 14th: The temperature was subnormal, 96° F., but went up again and ranged from 98 to 101° F. till death. Patient grew weaker and refused nourishment. Coarse râles were heard over the lungs posteriorly. The urinary secretion was free. The abdominal wound looked gangrenous, although the skin was united. January 19th: Patient died. Autopsy: The suprapubic wound was infected and a sloughing, rotten cavity, which extended as high as the umbilicus, was found between the skin and the transversalis fascia. There was a well-marked septic hypostatic pneumonia of the left lung. The kidneys showed a chronic diffuse nephritis, with secondary septic infection. The bladder was soft and necrotic and contracted. The cavity of the capsule of the prostate was not much affected, although no signs of repair were present. The perineal wound was soft and necrotic. The cause of death was septic absorption, chiefly from the suprapubic wound. Evidences of the infection appeared three days after the operation. The question arose, Was the patient infected during the operation (open wound in the perineum from perineal section present) or was he infected by his own urine (the urine was at no time very foul nor did it contain large quantities of pus)? The patient would probably have recovered if he had not become infected, although the laceration of the urethra was considerable in extent. The wound looked clean and the tabs of mucous membrane would have grown fast to the floor of the urethra or else would have sloughed off; the floor of the bladder was intact, the drainage perfect, and but very little urine came in contact with the wound in the prostate.

Results of the Bottini Operation.—Dr. H. H. Morton presented a specimen showing the results of the Bottini operation. The patient, J. M., seventy-eight years old, a painter by occupation, entered the hospital December 9, 1901. He has been unable to urinate naturally for a year past, and complains of a frequent desire to pass water and an inability to perform the act; he also has a good deal of tenesmus. Upon entering the hospital the patient could only pass from one to two drams of urine at infrequent intervals and practically had complete retention. The catheter introduced into the bladder drew off twenty-four ounces of residual urine. *Per rectum* the prostate appeared to be 1½ to 2 inches in diameter and hard. The cystoscope showed an enlargement of the middle lobe and a trabeculated bladder. The urine was found to be acid, cloudy, with a specific gravity of 1016. Slight sediment; pus cells present; no casts. December 17, 1901. Bottini's operation was performed.

No general anesthetic was used, but cocaine was injected into the urethra and the patient did not complain much of pain. After the operation he had to be catheterized twice a day for the first two or three days. Then he began to pass water and the catheter was used only in the morning, withdrawing eight ounces of residual urine. December 28th: Catheter used now once a day and withdraws from three to four ounces of residual urine. Passes water every hour during the day and five times at night. He is slow in starting the stream, requiring from five to ten minutes, yet he ejects a small stream with a good deal of force and some pain. January 18th: Urinates now six times daily and four times at night and passes a better stream than before the operation. Cystoscopic examination shows the middle lobe of the prostate with a cleft in the middle made by the Bottini operation.

February 10th: Patient has been up and about the ward and feeling comfortable until a week ago when he began to fail and died to-day probably from chronic cystitis and uremic fever. Complete autopsy not permitted. Autopsy: Bladder is black inside and contains a small quantity of thick foul pus. Many small necrotic areas, ⅛ inch in diameter, scattered about on

the surface. Numerous small sacculi, ¼ inch deep, one containing a small calculus. Traces of Bottini operation shown as follows: Necrotic areas at interureteric fold. Blade must have caught here and knife burned a superficial incision through interureteric fold. Middle lobe of prostate cleft in halves and necrotic area at apex of each half 1 inch in length and ½ inch wide. The left lateral incision visible as a cut lying to the left side. Knife missed splitting prostate (handle of instrument must have been elevated too much) and stripped bladder mucous membrane off surface of prostate. The anterior cut evidently not made at all. Knife simply moved backward in the urethra.

Bladder in bad condition prior to operation; cystitis was evidently made worse and was probably the cause of death. The middle lobe of the prostate was divided; the reduction in its size apparently occurred from the sloughing of the burned areas at the apices. It is probable that the operation proves curative through the contraction of the cicatrices following this sloughing. The difficulty of placing the instrument in the proper position, without seeing, is shown by the fact that the left lateral incision was made incorrectly, the anterior incision not made at all, and that during the posterior incision the beak of the instrument was too far in the bladder and burned through the interureteric bar, which, as it happened, did no harm but was unnecessary. Death occurred seven weeks after the operation. The patient's retention of urine, which was complete, was almost entirely relieved and if he had left the hospital a few weeks earlier, as he was perfectly able to do (he was kept in the ward because he needed bladder washing and because he had no home), he would have been entered on the statistics as cured. The autopsy showed that the curative result was brought about through the effect of one incision.

Dr. F. Cabot said that the Society owed a debt of gratitude to Dr. Morton for reporting the cases he had lost, for often more is learned from such reports than from reports of successful results. With regard to the Bottini method, he believed it to be unsurgical; the fact that one was not able to see just what one was doing damned the operation in his eyes. He believed that although good results came from the sloughing, others occurred later on through cicatrization or through the shriveling of the prostate as the result of the cicatrix. He called attention to the fact that the case might have been placed on record as a successful case and said that this gave food for thought.

Dr. Bierhoff said that the case was particularly interesting to him because he had of late been thinking over the question, not as to what were the indications for a radical operation, but as to what were the contraindications. One often hears reports of the cases operated upon radically, but seldom does one get reports of the condition of the other organs prior to operation. In Dr. Morton's second case he did not refer to any signs pointing to involvement of the kidney; in the first case he did. Personally he believed that pyelonephritis or nephritis was a contraindication for operation. He thought that these cases did better if some palliative treatment were used; often, when indications for radical operation were present, the application of some form of palliative treatment caused an improvement in the kidney condition. He believed that the existence of degenerative renal changes forms a distinct contraindication. Working in the dark had been practically done away with. He referred to certain instruments, those of Wossidlo of Berlin and those of Freudenberg and Bierhoff, which can be used under the guidance of the eye. These cannot be used in every case, unfortunately. There is going on abroad quite a discussion as to the technic of the Bottini operation—whether the finger ought to make counterpressure, etc. He thought that, before the current was turned on or the knife drawn from its sheath, one should satisfy one's self with the finger in the patient's rectum, that the point of the instrument is really behind the prostate and is distinctly to be felt here. He said that Freudenberg laid particular stress upon the point that the beak of the instrument should press firmly against the part to be cut; if that be done and if the beak of the instrument be situated directly behind the prostate and could be distinctly felt through the rectal wall, hooking firmly against the prostate, there would be no slipping away of the beak and one ought not to cut other than the prostatic tissues.

Concerning the belief that filling the bladder with some clear fluid would interfere with the heat of the knife, he would say that he always fills the bladder with boric-acid solution, and he has never found that it interfered with the heating of the knife, provided one hooks the beak of the instrument firmly against the prostate.

Dr. McGowan said that what most impressed him was the fact that the Bottini operation was inexact. He preferred enucleation rather than cutting.

Dr. Hotchkiss asked Dr. Morton if he knew that the median lobe had been left in doing the Alexander operation.

Dr. Morton replied that he did not attempt to remove it.

Dr. Hotchkiss asked if he could reach it with his finger.

Dr. Morton replied that he could, and that it was found to be quite small.

Dr. Swinburne asked whether, if the bladder was distended with air instead of water, the air would escape on account of the manner in which the instrument was heated.

Dr. Cabot said that he believed that the Bottini and other methods should be superseded by the method Dr. Fuller was now using, the suprapubic method, which enables one to get good drainage. One of the most serious objections to the Bottini method he considered to be imperfect drainage. In his operation the suprapubic and perineal tubes are left in position for some time and the granulation tissue was not disturbed. This washing out of the bladder corrected the cystitis.

Dr. Greene said he now had a case in the Workhouse Hospital, a man with a suprapubic fistula, who had no control over the sphincter muscles, and who urinated continually during the day. As soon as any urine gets into the bladder it dribbles out through the urethra. To remedy the suprapubic fistula a catheter was introduced; but still the urine dribbled out along the sides of the catheter, and whenever the patient assumed the reclining position the urine appeared through the suprapubic opening. This showed how difficult it was to keep the bladder thoroughly drained in cases of suprapubic cystotomy. Apparently, if the patient could be kept in the semi-upright position better drainage could be had.

Dr. Bierhoff referred to the statistics published in 1900 by Freudenberg regarding the success of the Bottini operation. The latter did not call a case cured that was not seen some months after operation, or who had ever so little residual urine, or who relied upon a catheter; in other words, the function must be restored and the cystitis cured before the patient was considered cured. The deaths reported were about 4¾ to 5½ per cent.; the cures were over 55 per cent. The ages of the patients had frequently been over seventy. The speaker had assisted Dr. Freudenberg in operating upon a patient sixty-nine years old.

Dr. Greene referred to bladder insufficiency owing to atrophy of the bladder muscles in cases that were operated upon for hypertrophied prostate, and said he did not see how such cases could be cured.

Dr. Lapowski asked if Dr. Bierhoff would operate in cases in which the bladder was infected and in which a purulent discharge and streptococci were present.

Dr. Bierhoff replied that he would not operate until the bladder had first been treated.

Dr. Morton agreed with the points brought out by Dr. Bierhoff. He thought it was a great mistake to operate upon a patient who was suffering from advanced renal disease. In every case of prostatectomy he examined the urine before operation to see that the kidneys were not badly affected. Such an examination was made in the case reported and but a little albumin and a few casts were found, showing but a slight nephritis; after the operation the patient passed from 50 to 60 ounces of urine, showing that the kidneys were not badly damaged. At the autopsy the kidneys were shown to be diseased but it was caused by an acute sepsis. He thought the point made of placing the finger in the rectum a valuable one. He always endeavored to hook the beak of the instrument before beginning to cut. He acknowledged that he could not always tell exactly where the beak was. In reference to Dr. McGowan's remarks regarding the Bottini operation not being exact, he asked what was to be done in cases in which there are complete retention and a hard fibrous prostate which demand relief. Perineal drainage in such cases is not of much value; one cannot enucleate the prostate and so Bottini's operation seems to answer the purpose in these particular cases. He had never tried filling the bladder with air, as suggested by Dr. Swinburne; it seemed to him that the air would escape. If a rubber band was tied about the penis that might prevent the escape of air, but it would interfere with the manipulation of the instrument. Dr. Morton thought it was necessary to sew the tubes in to prevent their shifting and that this made a perfect drainage by running water through them. He had found that in nearly every case in which a little cystitis was present the Bottini operation made the cystitis worse and, in one case, perineal section, with drainage for two months, was necessitated. He did not believe that one should consider the Bottini at any time as a light or trivial operation, because the mortality-rate is higher than is generally thought. He acknowledged that it is a difficult matter to keep the patient dry after a suprapubic cystotomy.

A New Irrigating Pan.—Dr. Swinburne showed a new irrigating pan to be used by the patient while sitting on the edge of the bed or on a chair.

Dilating Bladder with Air Prior to Using the Lewis Cystoscope.—Dr. Swinburne said there was no difficulty was experienced in keeping air within the bladder; the only difficulty was that in the majority of cases considerable pain was caused, a sort of "bladder colic" being produced.

SOCIETY OF ALUMNI OF BELLEVUE HOSPITAL.

Stated Meeting, Held February 5, 1902.

The President, Alexander Lambert, M.D., in the Chair.

Report of a Case of Removal of the Gasserian Ganglion.—Dr. John F. Erdmann presented a report of an operation done after the Krause-Hartley method on a patient sent to him on June 7, 1900. At the age of fourteen years the patient had developed, after a traumatism, a marked hunchback, and since then he had suffered from asthma. At the age of forty-one, while wiping his face, he felt a sharp pain in the region of the right ear, but it had disappeared and not returned for one year, when it had recurred under the same circumstances, and was so severe that he sought advice from a dentist and from a surgeon. The latter resected and excised Meckel's ganglion. Subsequently the pain became much more frequent and severe. All the usual local measures had been tried without relief. When first seen by Dr. Erdmann he was using three-quarters of a grain of morphine daily. June 30, 1900, he was placed upon a thorough course of iodide, but by July 30th the patient begged for operation as the pain was more severe and he was emaciating rapidly. On July 31st, under chloroform and ether, he was operated upon by the method of Hartley-Krause. There was troublesome venous hemorrhage during the operation, but finally the ganglion and its middle and inferior branches were removed. A small rubber drain was inserted. The temperature range was so peculiar that on the second or third day he was tempted to open the wound. The result of this was negative, and the same thing occurred a few days later. No opium or morphine was given after the operation until the eighth day and this probably explained the occurrence of some delirium. He was discharged at the end of the third week with a marked increase in weight, an excellent appetite, and free from pain; the opium habit was practically cured within three months. On January 4, 1902, the man had been deeply shocked by the death of his wife, and three days later he awakened to find himself slightly paralyzed on the left side. Since the operation there had been no pain and absolutely no eye symptoms. The speaker said that in the case previously reported by him in 1899 the patient had had absolutely no pain since that time. In quite an extensive report by Dr. Tiffany of Baltimore mention was made of the fact that in many cases disturbance of the temperature followed the removal of the ganglion. In his first case there had been some disturbance of the temperature, but it had not been so marked as in the second case. As far as the removal of the osseous portion of the flap was concerned, he did not think it made any difference because the flap became very thick and dense. He had removed it also and the patient had done well. Dr. Tiffany stated that he removed the osseous flap in all of his cases, simply leaving the periosteum, and that the patients did perfectly well.

Dr. Irving S. Haynes said that a case of this kind had been shown at the New York Surgical Society some years after the operation; there was very decided depression of the skull at the site of the operation. It seemed not improbable that there would be greater liability to pressure on the brain by leaving the bone than by removing it.

Importance of a Course of Laboratory Physics in the Study of Medicine.—Mr. M. C. Trowbridge said that he had written to about thirty-five medical institutions asking for information regarding the instruction given in physics. Answers had been received from thirty, and only three gave a laboratory course in physics. These three were the Barnes Medical College, Mo., Dartmouth College, N. H., and the Medical Department of the University of Virginia. To these should be added the College of Physicians and Surgeons, Columbia University, New York. In physics, laboratory work should be an organic part of a systematic course, consisting of lectures, demonstrations by the lecturer and qualitative and quantitative work by the students themselves. Such a course had been given for a number of years at the College of Physicians and Surgeons, New York, the laboratory portion being under his own charge. Each student was provided at the commencement of the term with a course list, in which were enumerated the experiments to be

made. The notes taken should be a synopsis of the work performed, and should be accompanied by diagrams. Each student performs twenty-five experiments, twenty of which are prescribed for him. Approximately 160 students took the laboratory course each year; hence the class was divided into four sections. Twenty-five experiments were performed in thirty-six hours, yet the students did perfectly satisfactory work. To each experiment was assigned a table, and the apparatus was kept there constantly in readiness. There was about one instructor to ten students. The general utility of the course was apparent because of the intimate relation of physics to medicine, to say nothing of the general value of such laboratory training. The experiments showed (1) the necessity of working with method and deliberation; (2) the value of precision; (3) the necessity for taking every factor of an experiment into consideration; (4) the liability to make mistakes in manipulation, and (5) the errors in the apparatus and in the experimenter. As many physical instruments were used in medicine, the practical value of such a course was obvious. Thus, the thermometer, the spirometer, the cyrtometer, the microscope and the spectroscope were used in medical work. The applications of electricity in medicine were increasing daily. Electricity was used for cauterization, the removal of tumors by electrolysis, for the illumination of cavities of the body, and for the production of the X-rays. The student became familiar in the laboratory course with batteries, galvanometers and switch-keys. In 1899 twenty-six medical colleges required a total of 4,000 hours of study before graduation in medicine, so that the laboratory course just described, which only occupied thirty-six hours, could not be said to be very time-consuming.

Etiological Classification of Varicose Veins of the Legs.—Dr. William S. Terriberry said that pathologically stricture of a valve caused (1) circular dilatation; (2) dilatation, with an actual lengthening of the affected vessel and considerable change in the walls and valves; (3) circumscribed fusiform dilatations of a portion of the diameter of the vein, forming an aneurismal sac, and (4) a number of dilated veins with aneurismal sacs in close proximity to become adherent. These different conditions might be regarded as successive stages of the process. The liability to thrombosis was greatest at the angles or pockets, or where the amount of motion was the greatest. The thrombosis was checked, according to Bennett, at the valves rather than at the nearest branch. Trendelenburg, basing his deductions upon experiments on varix of the internal saphenous vein, claimed that varicose veins were dependent upon regurgitation through the valves of the internal saphenous, with excess of pressure from above downward, there being a column of blood extending from the diaphragm to the saphenous opening without any supporting valves. Trendelenburg believed that every case of varicosity of the superficial veins was caused by regurgitation by gravity through the more or less incompetent valves of the saphenous veins, but in the opinion of Dr. Terriberry gravity had been blamed too much. The column of venous blood ascending was supported by the transmitted power of the heart's action at whatever level. So long as the propelling force was able to overcome gravity and drive the blood onward, the venous valves would not be called upon to act; but when there was obstruction, dilatation was caused primarily by the heart's action and by gravity secondarily.

If this obstruction became permanent, the vein would in time become permanently dilated and the valves incompetent. When there was stenosis above the saphenous valve, it was due either to actual narrowing of the lumen of the superior vessels or to increase of the intra-abdominal pressure. In another class of cases following obstruction from constriction, thrombosis or obliteration of a large number of veins inferior to the saphenous valve, there resulted regurgitation through the saphenous valves. There being a limit to the distensibility of the walls of the vein, an increase in the speed must of necessity follow. There was a third class of cases caused by obstruction of veins as a result of thrombosis or local constriction. Such cases were due to small anastomosing connections of the deep veins. There were, then, three groups of cases, viz., (1) those due to regurgitation following stenosis above the saphenous valve; (2) those due to regurgitation with stenosis inferior to the saphenous valve, and (3) those due to stenosis without regurgitation.

Dr. Alexander Lambert said that some years ago he had been asked to go with an engineer into a caisson to note the effect of the compressed air upon varicose veins. As the engineer came out and the air became thinner and the pressure less, the bulging of his varicose veins was something extraordinary. This engineer had worked a great deal in the caisson, but had not had the caisson disease because of his great care in coming out of the lock.

Dr. Robert T. Morris said that mention had been made of the return flow being entirely dependent upon the force of the heart. He asked whether the older idea of the aspirating power of the heart had been entirely abandoned. In doing Schede's operation for varicose veins a circular incision was made about the leg through the skin, veins and subcutaneous tissue. Numbers of very large veins were frequently widely opened. An Esmarch bandage was applied before the incisions were made; if this circular incision were made without the bandage, the patient would bleed to death in a few minutes. If the veins were divided freely and the Esmarch bandage removed without suturing, the flow from the veins would be found not to be excessive. If very slight pressure were made upon the veins which had collapsed after being emptied by the Esmarch bandage, the hemorrhage would cease. In a number of cases in which he had used Schede's operation he had simply sutured the skin without taking the trouble to ligate the large veins, and by making very slight pressure he had been able to control the hemorrhage. Practically, however, he had found that there had been a speedy recurrence of the former condition because the ends of the veins had found each other after the operation by cell replacement. It was his custom now to ligate the open veins, not for the purpose of controlling hemorrhage, but to prevent recurrence. In cases of varicose veins in which there was fairly wide dilatation, due to the hydrostatic pressure of the column of blood in the vein, there was hypertrophy of all of the structures at first, but later on there was a dilatation, and it did not seem to him that one could hope for cure from palliative measures after the hypertrophy had passed into the stage of degeneration. He asked the method of determining just when this stage had been reached. In the earlier stages palliative measures were quite effective. Alternate douches for thirty seconds in ice water and very hot water, kept up for two or three minutes twice a day, were very effective, as were also massage, the faradic current and good support. Many of these cases could be well treated without operation.

Dr. Terriberry said that the classification by causes in this particular disease was important on account of its bearing upon the choice of operation. Many observers claimed that any operation which would cut off the column of blood from above was sufficient to cure all cases. Any one who had studied carefully the reported cases would find that many of them were not cured in this way, and that in the majority of instances the failures

were in cases in which varicosity had resulted from constriction below the saphenous valves. The regurgitation might be eliminated by the Schede or Trendelenburg operation, but the varicosity remained and the force of the heart's action was expended on the wall. The aspirating power of the heart, he thought, depended upon the relative pressure, and the latter in turn depended upon the force of the heart transmitted by the elastic recoil of the arteries. It was highest at the aorta and diminished toward the end of the arterial system. A great deal of it was lost in the capillaries, but there was still enough pressure left in the beginning of the venous system to force the blood onward. Under the influence of inspiration there was, of course, an aspiration in the large veins, but when expiration took place, there were compression and a consequent increase in pressure in these veins. If there was a varicosity in the veins high up in the venous system, this might have an effect when the pressure became negative. The lack of hemorrhage mentioned by Dr. Morris is probably due to the collapse of the emptied veins caused by atmospheric pressure acting through the integument.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held February 4, 1902.

The President, Joseph Collins, M.D., in the Chair.

A Case of Monocular Exophthalmos.—Dr. J. Arthur Booth presented this case and raised the question as to whether one was justified in making the diagnosis of Graves' disease. The patient was forty-seven years of age and had never had any serious illness. She had been well up to last fall, when she noticed a blurring of the vision and a change in the appearance of the eye. There was no history of fright; the patient stated that three months ago the left eye was struck by the foot of an infant. Examination showed no enlargement of the thyroid; pulse 96; no decided tremor. Dr. David Webster found both fundi normal and the action of the eye muscles normal. There was retraction of the upper eyelid of the right eye with marked exophthalmos.

Dr. B. Sachs said that he had at present under treatment a married woman, about twenty-three years of age, who after pregnancy had developed unilateral exophthalmos. The case was identical with the present one except that the exophthalmos was on the other side. There was no goiter, and on coming under treatment the pulse was 132. Under treatment, consisting chiefly of rest in bed and the use of mild tonics, the pulse came down to 90 and was no longer intermittent, and the exophthalmos was slightly diminished. In addition, this patient presented the peculiar gastro-intestinal symptoms of Graves' disease, and, in the absence of any other serious condition he could only make the diagnosis of unilateral Graves' disease.

Dr. W. M. Leszynsky said that he had seen two similar cases. One occurred in a man who had exophthalmos, retraction of the upper eyelid and some tachycardia. In the course of six months the usual symptoms of Graves' disease developed and the case ran the usual course. In the other there was unilateral exophthalmos and retraction of the upper eyelid with slight goiter, but without tachycardia. The case followed the usual course of Graves' disease. It did not seem to him unusual in the early stage of Graves' disease to find the exophthalmos only on one side.

Dr. J. Arthur Booth thought it was rather unusual for the eye alone to be affected in the beginning; more commonly there was some tachycardia as the first symptom.

A Case of Central Hematomyelia.—Dr. I. Abrahamson presented a man of forty years, a Russian tailor. The man had fallen and struck the back of his head on the floor some weeks previously and a week and a half later had noticed numbness of the little finger of one hand; twenty-four hours after this the entire upper extremity was numb, and the next day both lower extremities were numb and weak; on the fourth day of this trouble there was complete inability to move. The special senses were normal. There was extensive muscle-wasting while in bed, although there was no fever. He recovered in a very short time. Examination showed the pupils equal and the ocular movements normal. There was a tremor of the facial musculature on one side; the tongue was drawn to the right; the reflexes of the upper extremity were exaggerated, especially the triceps. There was a marked flabbiness of the musculature and wasting, especially around the shoulders. The knee-jerks and Achilles jerks were exaggerated. There was no spasticity. The volume of the left lower extremity was much greater than that of the right. There was no limitation of the visual field, and no Romberg symptom. On rising from a chair it was necessary for him to assist himself with his hands.

Dr. Joseph Collins said that he had had this case under his observation, and the only diagnosis seemed to him to be a central hematomyelia with the cleavage in an upward direction. The comparatively mild traumatism, the rapid onset of the symptoms, the rapidity of the recovery and the widespread involvement all seemed to him to point to this diagnosis. About two weeks ago the abnormal condition had been much more marked than now. There had been great difficulty in rising from a chair, and he would sit down very suddenly. There were no objective sensory disturbances.

A Case of Cerebral Endarteritis, Probably Syphilitic.—Dr. W. M. Leszynsky presented a Hungarian woman, twenty-two years of age. There was no history of rheumatism, trauma or syphilis. Several times recently there had been transient paresis of the left arm and leg, and there had been some regurgitation of food. Shortly before coming under his observation there was severe headache and vertigo associatd with fever and followed by marked ptosis of the left eye. Examination in August showed partial ptosis of the left eye with vertical diplopia; only the left superior rectus muscle was affected; the vision in both eyes was normal. The fifth nerve was normal objectively. Innervation of the facial muscles was feeble on both sides, and there was slight facial paralysis on the right side. She was treated with mercury and iodide, together with galvanism and the use of strychnine internally. In ten weeks the ptosis and diplopia had disappeared. The ptosis then attacked the right eye and in three days became complete. The levator was the only muscle affected. The iodide of potassium was resumed, and in four weeks this muscle had almost completely recovered. One month later the lefgt eye was again attacked with ptosis; there was slight vertigo, but no diplopia. At times it was necessary to make several efforts at swallowing before succeeding; she still complained of left-sided headache, and after talking for some time she found it almost impossible to speak, but ability to do so would return after a few minutes' rest. She was now receiving twenty-eight grains of iodide three times a day. There was no history or evidence of syphilitic infection. The case seemed to be a peculiar instance of cerebral endarteritis, probably syphilitic. The iodide had very little effect in controlling the pain.

Cerebrospinal Syphilis.—Dr. Leszynsky also presented a man thirty-three years of age, a driver by occupation. He had been first seen by the speaker in

November, 1899, and up to three months before that had been well. He then experienced numbness in the left side of the face with slight twitching of the facial muscles. Two months later there was diminished vision in the right eye with occasional diplopia. Four months after the numbness began, the first three molar teeth in the right upper jaw became so loose that they were removed with the fingers. He was the father of six healthy children. According to the history, he had many years ago contracted a chancre, but no marked secondary symptoms had appeared. The pupils were found to be markedly contracted and rigid. There was no anesthesia of the conjunctiva; there was good vision in each eye; both fundi were normal. The innervation of the facial muscles was normal and there was no tremor. Mercurial ointment and iodide of potassium were used at first and later strychnine. Three months later he complained of vertigo and diplopia and was found to have complete paralysis of accommodation. At the end of two months he was much improved and disappeared from observation. After sixteen months he returned, and stated that fifteen months previously he had fallen through a hatchway, but had only been severely shaken up. In July, 1901, he was thrown to the ground by a man jumping upon his head from a height. On examination, there was found to be complete paralysis of all branches of the third nerve; both pupils were rigid and he was blind in the right eye. There was advanced atrophy of both optic nerves. He had been taking iodide and strychnine in injections. In this case of cerebrospinal syphilis the optic atrophy was apparently of a primary degenerative type. Strychnine was administered in gradually-increasing doses up to the toxic effect, but it had no beneficial action, and this had been the speaker's uniform experience with it in these cases. The case was of forensic interest because the man was trying to substantiate a claim that the blindness had resulted from the traumatism to the head.

Dr. B. Sachs said that the diagnosis could only lie between cerebrospinal syphilis and tabes, pure and simple. In the former, if the optic nerves were involved there would be a distinct optic neuritis. The important question was as to whether there had been a primary optic degeneration. According to the history, the case was probably one of cerebrospinal syphilis. The first case also seemed to be one of cerebral syphilis, but he doubted if it were an example of syphilitic cerebral endarteritis; it was more than probable a thickening in patches of the meninges of the nerves as they emerge from the base of the brain.

Dr. Leszynsky said that on account of the transient character of the symptoms it seemed to him that they were, in all probability due to some interference with the circulation. The temporary attacks of aphasia, difficulty in swallowing, and the trouble with the third nerve pointed to some interference with the nutrition of the nuclei. If this interference were with the nerve trunk itself it would be unlikely for the localized meningitis to select certain fibers of the nerve and interfere with the nuclear distribution. In the second case, both Achilles reflexes were present; there were no sensory symptoms—in short, nothing to indicate the presence of tabes.

Multiple Sclerosis.—Dr. I. Abrahamson presented two cases suggesting multiple sclerosis, though presenting other symptoms. The patients were seventeen and sixteen years old, respectively, a sister and brother. Both parents were well. The children were born without the aid of instruments, but early showed an unsteady gait, slowness of speech and nystagmus. Both children exhibited pronounced stigmata of degeneration. On examination, the gait was unsteady, the pupils were equal, the ocular movements slow and jerky, and nystagmus was present in all positions. At times, Babinski's symptom was obtainable. There were no sensory disturbances. The speech was slow and monotonous, and there were marked mental defects of the nature of a mild dementia. The fact that these two children, together with another, all belonged to the same family was a point against the diagnosis of multiple sclerosis.

Dr. C. L. Dana said that if these cases were not to be called multiple sclerosis he did not think it would be possible to make that diagnosis from the clinical picture.

Dr. Joseph Fraenkel said that he had seen the boy when he was brought to the Montefiore Hospital, and had made the diagnosis of multiple sclerosis, but after having watched the case further and obtained a complete history he had been in doubt about the correctness of this diagnosis. At the time of admission the spastic symptoms were very much more marked than at present.

Dr. Sachs said that family forms of multiple sclerosis had been described, yet they did not entirely correspond with the typical picture of multiple sclerosis. They resembled somewhat the Marie type, but he would not make that diagnosis. A progressive disease of this sort occurring in a family with dementia had been reported by one of the northern European writers.

Dr. Collins said that he would hesitate long before diagnosticating these cases as multiple sclerosis, for the reason that this was opposed to our conception of multiple sclerosis as a pathological entity. It was now looked upon as a disease of early adult life of the nature of a late infection or organic neurosis. In the cases just presented there was, in all probability, a teratological condition. To account for the symptoms there would have to be a large sclerotic area of the poles of the anterior hemispheres, while the posterior and middle parts would have to be almost free, as the special senses were well developed.

Dr. Dana said that as dementia paralytica could be associated with multiple sclerosis in adult life, it was possible that the defective mental development might exist in childhood.

Dr. J. Ramsay Hunt reported the case of a widow, fifty-three years of age, who had been admitted to the Montefiore Hospital in October, 1886. At this time her disease had lasted for several years. Speech was slow and stammering. She had a spastico-ataxic gait, the Romberg symptom, slight weakness of the upper extremities with ataxia, and considerable motor weakness of the lower extremities. The knee- and ankle-jerks were present and lively on both sides, and the pupils were equal and active on both sides. There were no sensory disturbances and no rectal or bladder symptoms. The ophthalmoscope showed an atrophy. In January, 1899, it was found that she could neither walk nor stand; speech was stammering and syllabic; there was marked intention tremor in the upper extremities; nystagmus was present in all directions except downward. The motor power was defective in the upper extremities and there was resistance to passive movements, especially in the legs. The right knee-jerk and left Achilles-jerk were absent. The plantar reflex was present on the right and absent on the left. On postmortem examination, the anterior border of the calvarium showed a nodular eburnation. The fissures were widened. The stained tissues showed an increase of gliar cells and leucocytes in the gray matter. The cells showed distinct atrophic changes and were somewhat sclerosed. The meninges were thickened and infiltrated with round cells. In the cord were found disseminated plaques of sclerosis. Nowhere in the cord were any distinct signs of inflammation. The specimens from this case were exhibited under the microscope.

Discussion on the Absolute and Relative Frequency of Multiple Sclerosis.—Dr. C. L. Dana said that among 3,000 private cases of which he had histories there were only ten cases of multiple sclerosis. Of about 600 cases at the out-door clinic during the past year there were only two cases diagnosticated as multiple sclerosis, and even these were questionable. In Bellevue Hospital itself 12,000 patients were received annually, and one of his assistants was constantly on the watch for cases of nervous disease, yet he had not found more than one or two new cases of multiple sclerosis each year. It was evident, then, that multiple sclerosis was very rare in private practice and decidedly more rare than in the clinics of Europe. It was possible that mistakes in diagnosis were made in some cases of so-called acute or subacute transverse myelitis coming under observation as chronic transverse myelitis. Some of these cases would probably ultimately prove to be examples of multiple sclerosis; of those he had been able to follow for many years none had terminated in this way. Other cases of multiple sclerosis might have been recorded as ataxic paraplegia, though he did not make this diagnosis. He could call to mind four of these cases in which there was really a combined sclerosis due to some secondary anemia or toxemia. Then there were cases of sporadic forms of retrobulbar neuritis which perhaps develop later into multiple sclerosis. From his experience he was compelled to believe that multiple sclerosis must be more rare here than abroad, possibly owing to the better surroundings of the masses.

Dr. Graeme M. Hammond said that he had spent considerable time in examining the records of both private and dispensary practice. He had examined 3,000 private records and 7,000 records from the clinic, extending over the past ten years. In the former there were 729, or about 25 per cent., with organic diseases. Of these cases, fifteen, or about 2 per cent. had multiple sclerosis. In the clinic cases there were 2,400 of organic diseases, and of these thirty-two had multiple sclerosis, or 1.33 per cent. He could not agree that there was a greater percentage of multiple sclerosis cases in dispensary practice. Of the combined private and dispensary cases forty-seven had multiple sclerosis, or 1.5 per cent.

Dr. Goodhart reported for Dr. M. Allen Starr that he had examined 10,056 cases in the clinic and had found twenty-seven recorded as multiple sclerosis. In six of these the diagnosis was doubtful—in other words, there was one undoubted case in 475. Of the 4,809 males there was one case of undoubted multiple sclerosis in 437; while of the 4,898 females there was one such case in 700. With regard to the age, the records showed that among the males there was only one occurring after the age of sixty, while among the females all developed the disease under thirty-one years of age, the earliest case occurring at the age of sixteen months.

Dr. Sachs said that he had examined the records of 2,000 cases in private practice and had found thirteen undoubted cases of multiple sclerosis and two questionable ones. There were forty-one of tabes dorsalis, sixty-nine of cerebrospinal syphilis, thirty-eight of general paresis, fourteen of intracranial tumors, fifteen of paralysis agitans, thirty-seven of apoplexy and fifteen of infantile cerebral palsy. He thought a faulty impression had been found of the relative frequency of the disease in Europe. According to one of the latest European works, the author states that he had seen 5,500 private cases of nervous disease, and in this number had met with thirty-eight cases of multiple sclerosis. This would give one in 144, whereas Dr. Sachs said his own experience gave one in 150. It was most important in considering such figures to know from what classes the material had been drawn. Many cases diagnosticated in this country for the time being as chronic myelitis were diagnosticated in Europe as incipient cases of multiple sclerosis before the characteristic symptoms had developed. With regard to the differential diagnosis, the speaker said it was important to differentiate multiple sclerosis from multiple cerebrospinal syphilis and also from general paresis, particularly in the later stages. Multiple sclerosis usually began earlier than general paresis and the latter was a much more progressive disorder, the dementia being much more marked. In several cases of cerebral infantile palsy he had been in doubt as to whether there was multiple sclerosis present. There were some cases which had begun as multiple sclerosis and had gone over distinctly into paralysis agitans. He had seen two or three cases in which there was considerable doubt as to whether the correct diagnosis was neurasthenia or multiple sclerosis.

Dr. Leszynsky said that he had no statistics to present, but he would agree with the others that multiple sclerosis is comparatively rare in this country.

Dr. B. Onuf said that he had made the diagnosis of multiple sclerosis in a much larger proportion of cases than the others, for he had seen in hospital between 500 and 600 cases and had made the positive diagnosis of multiple sclerosis in eight cases.

Dr. Edward D. Fisher sent a communication saying that in his clinic at the University, during six years, he had seen out of a total of 2,451 cases of nervous disease, eight cases of multiple sclerosis.

Dr. Collins said that in 1901, 1,470 cases of nervous disease had been seen at his clinic and this number furnished five cases of multiple sclerosis. In 1900, 1,368 cases were seen, of which five were multiple sclerosis. In 1899, there were 1,400 cases, five of multiple sclerosis; in 1898 there were 1,270 cases with three of multiple sclerosis. Thus, in the four years the clinic had been under his personal direction there had been approximately 6,000 cases of nervous disease, with nineteen cases of multiple sclerosis. During this period there had been thirty-seven cases of locomotor ataxia and twenty-nine of paralysis agitans. From 1890 to 1897 there were twenty-eight cases of multiple sclerosis in a total of about 4,000 cases of nervous disease. He had notes of eight cases of multiple sclerosis seen in the City Hospital and not included in the previous figures. This hospital devoted about seventy-five beds to nervous disease, and in this service he had met with about one case of multiple sclerosis a year. In his private practice he had made the diagnosis of multiple sclerosis four times only. According to his own experience, therefore, multiple sclerosis is a very rare organic disease of the nervous system. He had found paralysis agitans one and a half times more frequent and tabes dorsalis about twice as frequent as multiple sclerosis.

Dr. J. Fraenkel said that the statistics of the Montefiore Hospital confirmed very closely those already presented. Out of 2,100 patients at this institution during the past ten years, about half of them being cases of nervous disease, there had been only eighteen cases of multiple sclerosis. He had been very conservative in making the diagnosis of multiple sclerosis in these cases. Out of about 160 cases of nervous disease at present under treatment there, about thirty-five were cases of tabes and nine cases of multiple sclerosis.

BOOK REVIEWS.

The Standard Medical Directory of North America for 1902. Quarto, 925 pages. Illustrated. G. P. Engelhard & Company, Chicago.

This is certainly a splendid volume and the publishers are to be congratulated on their enterprise. The

many points of excellence render this book easily the best in the field. Its form is especially commendable and its many ingenious features stamp it at once as practicable, authentic, even indispensable.

In addition to its directory of practising physicians in the United States it includes those of Canada, Cuba, Mexico and Central America and further there are included careful and for the most part accurate lists of the medical officers of the Army and Navy, Medical Societies, Medical Colleges, Medical Laws and Boards, Medical Publications, Books and Periodicals, Hospitals and Sanitariums, Mineral Springs, Drugs and Medicines, Medical and Surgical Products, Manufacturers, Life Insurance Companies, etc., etc. In fact, there is almost everything that a medical directory should contain.

Certain omissions there are, and a distinct number among physicians' names, but for a first edition, the results are truly wonderful. Praise alone is its due.

Clinical Hematology. A Practical Guide to the Examination of the Blood with Reference to Diagnosis. By John C. Da Costa, Jr., M.D., Assistant Demonstrator of Clinical Medicine, Jefferson Medical College, Hematologist to the German Hospital. P. Blakiston's Son & Co., Philadelphia.

Pathognomonic blood-findings are as yet confined to leucemia, malaria, relapsing fever and filariasis, yet in many conditions the study of the blood adds very important information to that obtained by other methods. This book by its elementary fulness of detail will render such study possible to the many instead of to the specialist only. The working parts of the various kinds of apparatus and their manipulation having been studied minutely, the author plunges, in the first section, into the methods of obtaining the blood, of estimating its alkalinity, specific gravity and hemoglobin, and of counting and staining its cellular elements. The nature and function of normal blood as a whole and departures from the normal fill the second section. The chapter on the leucocytes is at once the most important and the best handled. Leucocytosis is considered as to the absolute increase in the number of white cells and the relative increase of any form of cell; a long list of diseases and drugs which affect the leucocyte-count is appended. Lymphocytosis is attributed to many different conditions, though it is not often marked except in lymphatic leucemia and whooping-cough. Sections follow on the diseases of the blood and the anemias of infancy and childhood, and then a long section is devoted to the detailed study of the blood in appendicitis, cholelithiasis, diabetes, enteric fever, erysipelas, malaria and about sixty other conditions. The Widal reaction is described and figured under enteric fever, the writer regarding as positive a reaction with 1-10 serum, though conservative men abroad and in this country require a 1-40 serum reaction. The recent work of Durham and others on serum reactions in paratyphoid infections is not mentioned.

The colored plates and figures in the text are good enough to whet the appetite for more, and the reading-matter in general is conservative, correct and up-to-date. The book deserves high commendation.

Rational Hydrotherapy. A Manual of the Physiological and Therapeutic Effects of Hydriatic Procedures, and the Technique of Their Application in the Treatment of Disease. By Dr. J. H. Kellogg, Superintendent of Battle Creek Sanitarium. F. A. Davis Company, Philadelphia.

This forbidding looking volume of 1,200 pages "aims to present in a more systematic and comprehensive way than has heretofore been undertaken the rational hydrotherapy which has been built up within the last century, and to record the fruits of the author's experience and observations." One might legitimately suppose that a volume of 1,200 large pages would provide ample space to set forth all that the practising physician should know about the use of water in the treatment of disease, but the author thinks otherwise. He says he hopes to publish another volume in which rational hydriatic treatment of individual disease will be discussed.

The book is divided into four parts. Part I. is devoted to a historical note, to the physics of water, air, heat, and light in relation to hydrotherapy, the larger portion of which seems irrelevant; to anatomy and physiology in relation to hydrotherapy about 50 pages, which, if properly pruned and compressed, would undoubtedly reveal many facts worth possessing; to the physiological effects of external and internal application of water; to the physiological effects of friction or mechanical irritation of the skin, and to the physiological effects of light. The relevancy of the latter topic is difficult to determine.

In Part II. the general principles of hydriatics, the therapeutic effects of hydriatic applications, the practical employment of hydrotherapy, and hydriatic institutions are discussed. Part III. is devoted to the technic of hydrotherapy and Part IV. to hydriatic prescription-making.

It is difficult to characterize this volume for it is not wholly without merit. A vast amount of labor has been expended upon it. It lacks particularly the impress of individuality and the stamp of homogeneity. If it had been properly "blue penciled," compressed rewritten with a clear perspective of the relation of hydriatics to the science of medicine and the art of therapy, and presented in a volume of, let us say, 300 pages, it would be deserving of most favorable consideration. As it stands now it most unfavorably impresses the reviewer, an ardent advocate of hydrotherapy, and he fully believes that the deserved reputation of water as a curative agent is not at all enhanced by such publications. Will any one, for instance, fail to recognize the absurdity of describing upward of 200 different hydratic procedures? Why not describe 300 or 600? If one can think out 200 ways he can easily think out double that number, for he has what may be called a numerical faculty. The author's judgment and scientific perspective are not always displayed to advantage in the lugged-in references to the perniciousness of tea, coffee, alcohol and tobacco, often wholly irrelevant. His remarks on these aids to wholesome living and high thinking do credit only to a certain type of mind.

International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, etc. By Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, U. S. Volume IV., Eleventh Series, 1902. J. B. Lippincott Company, Philadelphia.

The present volume of the "International Clinics" contains some very interesting practical articles. The opening special article, "Remarks on Strychnine," by Dr. Jacobi of New York, contains some valuable hints for the practitioner. We venture to quote a very suggestive passage: "This case would prove that the modern maxim, 'Simplicity of prescription, only one drug at a time, no polypharmacy, rely on Nature,' has its unscientific and ridiculous side. Muscle, serous membrane, vagus and sympathetic (there is question of a

heart case) may be affected coincidently (*sic*) or some of them at the same time. Rely on digitalis alone? Yes, if you be sure you want nothing but the stimulation of the pneumogastric. On strychnine alone? Very well, if you want a vasomotor stimulus? Alcohol? If you want to dilate blood-vessels in conditions of spastic anemia occasioned by fright, chill, or sepsis? Atropine? If you have to combat diminution in the number of cardiac contractions. Thus, I might go on teaching the necessity of combining medicines in combined conditions."

There are some excellent articles from foreign contributors. For example, "The Treatment of Mucomembranous Colititis," by Professor Albert Mathieu; "A Modified Technique in the Spinal Injection of Cocaine," by A. Guinard, M.D.; "The Pathogenesis and Prophylaxis of Varicose Veins," by Professor Pierre Delbet; "Clinical Observations on Certain Diathetic Conditions," by Sir Dyce Duckworth; "The Etiology and Treatment of Acute Myelitis," by Professor G. Marinesco, and "Splenectomy for Malarial Cachexia," by Professor Thomas Jonnesco.

The volume closes with a discussion of the methods of keeping case records in private practice, in which Drs. Frederick Packer, Crozer Griffith, Judson Daland, J. K. Mitchell, John H. Musser and Alfred Stengel take part. The article on a description of the methods of investigating the action of drugs scarcely seems to deserve a place in a volume devoted to clinical medicine. The methods described are entirely those of the laboratory and of animal experimentation and have an academic, but scarcely a practical interest; besides they are only the usual methods to be found in any textbook of physiology.

The Surgical and Medical History of the Naval War Between Japan and China During 1894-1895. Translated from the Original Japanese Report under the direction of Baron Saneyoshi, Director General of the Medical Department of the Imperial Japanese Navy, by S. Suzukel, Deputy Inspector General of Hospitals and Fleets, Imperial Japanese Navy, Tokio, 1901.

As a work of great interest to military and naval medical men particularly, and but little less so to medical practitioners in general, this work stands out in high relief.

Its contents are well arranged. The battles are first described and then follow brief histories of the killed and wounded, the different regions of the body affected being taken up in their general order. Statistics of Injuries makes a third chapter; Causes of Wounds and their Classification a fourth; Complications, Management of the Wounded, Diseases and Injuries, Sanitary Conditions During the War, and Work in the Naval Hospitals, are the titles of the several remaining chapters.

It is an interesting record, well and picturesquely told and is worthy of much commendation.

Studies in the Psychology of Sex: Sexual Inversion. By Havelock Ellis. F. A. Davis Company, Publishers, Philadelphia.

The present volume of studies in the psychology of sex, the second of the series, is the book that aroused so much opposition on its first publication in London. The prosecution was initiated by the police against a bookseller who sold the book and the Recorder of London, sitting as a judge, finally decided that it was not a scientific work and ordered it to be destroyed. Though this was an unfortunate decision, the author did not care to act in opposition to the laws of his country even as interpreted by amateur judicial experts and declared his intention not to publish any of the further volumes in England.

Needless to say, though the subject may have intensely objectionable features and may certainly not be meant for general reading, it must receive due treatment if medical men and others whose duties require their being brought in contact with sexual perverts shall realize just what the condition is and how to be appreciated. The names of the authorities on the subject, Casper, Ulrichs, Kraft-Ebing, Moll, Schrenck-Notzing and Féré, are too widely and favorably known to permit the thought that they were seekers after notoriety and not true scientists investigating a forbidding but none the less valuable problem in mental pathology.

The present volume contains an excellent review of the subject of sexual inversion to date without indulging in too great pruriency of detail, certainly not any more than is necessary for a proper understanding of the subjects and with suggestions as to the prevention of homosexuality, with special regard to the influence of schools and the treatment of sexual inversion, that cannot but prove of great practical usefulness.

Mr. Ellis' conclusion as to the attitude that must be assumed towards sexual inversion is characteristically straightforward. He puts off the attitude of moral superiority which is common in the literature of this subject and refrains from pointing out how loathsome this phenomenon is, or how hideous that. He says very truly and pertinently. "The physician who feels nothing but disgust at the sight of disease is unlikely to bring either succor to his patients or instruction to his pupils Pathology is but physiology working under new conditions. The stream of Nature still flows into the bent channel of sexual inversion and still runs according to law."

A Text-Book of Diseases of the Ear, Nose and Throat. By Charles H. Burnett, M.D., E. Fletcher Ingals, M.D., and James E. Newcomb M.D. J. B. Lippincott & Co., Philadelphia and London.

The combined effort of these three distinguished authors has resulted in producing a book of unique interest and value. The subject-matter is well handled throughout, there is less unevenness than would be expected, and several of the chapters are masterpieces of clearness, comprehensiveness and practicality. The publisher should also be congratulated upon his part.

Several features of the work call for special mention. Of the 220 pages upon the ear, 75 are devoted to describing its anatomy. This at first would seem disproportionate. No better exposition of the theme, however, has ever been written, while the general ignorance upon the subject which exists justifies the foresight of the author in thus wisely calling attention to it. It is not his fault that the chapter on chronic catarrhal otitis media is unsatisfactory. The baffling nature of this most serious and elusive condition, the difficulty of the subject, and in general the deplorable inefficiency of our present knowledge of this distressing ailment are silently emphasized by what the best authority of his time has been obliged to leave unsaid. The chapter on acute purulent otitis media is classic. It should be learned by heart by every practitioner of medicine. It is sound, forceful and clear and cannot fail to be of great practical value. Chronic otitis media and its sequelæ, otitic abscess and the graver conditions associated with this subject, are ably dealt with. The somewhat radical views expressed regarding removal of the ossicles, especially of the incus, should be acted upon with conservatism by all not eminently qualified to

apply them. Given distinguished ability in diagnosis, exhaustive knowledge of the regional anatomy, combined with highest technical skill, the value of the general results of these operations is still *sub judice*. It would be unfortunate if the average reader were to suppose the removal of the incus were advisable in any but the most experienced hands.

The author of the section on diseases of the nose and nasopharynx has not contented himself with giving an abridgment of his already well-known work, but has presented the subjects of his department with remarkable freshness and success. The two chapters upon diseases of the accessory sinuses offer the best presentation of this difficult topic which has ever appeared. The subject-matter is terse, comprehensive and accurate, the style clear and direct, and the illustrations full and remarkably instructive.

The chapter on deflections of the nasal septum is less satisfactory. Strange to say, the Asch operation is decried, priority for it is denied, and even the name of its distinguished originator is mutilated. In point of fact, the crucial incision through the septum suggested by Adams bears about the same relation to the method of Asch as does the crude and ineffective tube of Bouchut to the perfected system of intubation of O'Dwyer. Adams' operation was a complete failure. To Asch is due the credit not only of his own admirable suggestions, but of much of the stimulus under which recent advances in the same line have been made.

The other subjects of this section are ably presented. Greater geographical scope in the mention of resorts favorable to hay-fever patients, however, would seem desirable. With regard to the prescribing of snuffs and solutions containing cocaine to patients suffering from various forms of coryza, the views of this author are open to severe censure. It is time that public attention should be strenuously turned to the great danger of this almost certain method of establishing the most pernicious habit of the age.

The most evenly constructed section of the book is that on diseases of the larynx. It is evidently from the hand of one who has completely mastered the clinical as well as the literary side of the work and it fairly places him among the foremost writers of the day. The chapter on tuberculous laryngitis is particularly valuable.

The illustrations are in general excellent. It would be difficult to find a treatise better suited to practical needs, more comprehensive or more thoroughly abreast of the time.

Outlines of Anatomy. A Guide to the Methodical Study of the Human Body in the Dissecting-Room. By Edmund W. Holmes. Second Edition. Press of The New Era Printing Co., Lancaster, Pa.

Dr. Holmes is well known to thousands of medical students and physicians as a thoroughly practical teacher of anatomy by dissection. His book partakes of his character. It deserves the popularity that demands a second edition in five years. It can be recommended as a handy guide to dissection.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S., Lecturer on Anatomy at St. George's Hospital Medical School. Edited by T. Pickering Pick, F.R.C.S., Consulting Surgeon to St. George's Hospital, etc., and Robert Howden, M.A., M.B., C.M., Professor of Anatomy in the University of Durham, Examiner in Anatomy in the Universities of Durham and Edinburgh, etc. A Revised American from the Fifteenth English Edition. Lea Brothers & Co., Philadelphia and New York.

"Gray's Anatomy" is so well known that there is little need to say anything further of it and to praise it seems, indeed, like gilding refined gold or painting the lily. It has stood the test of time for nearly half a century and has demonstrated beyond all cavil how well Henry Gray knew how to write a text-book of anatomy.

Something should be said, however, about this new American edition. It is worthy of the old text-book at the beginning of a new century. The publishers in their prefatorial note say that anatomy is far from stationary even in its facts or in improvements in the method of their presentation. Hence, any work which would faithfully reflect the existing position of the science must be revised at comparatively frequent intervals. Fortunately for students and practitioners, "Gray's Anatomy" enjoys a continuous demand rendering frequent revision possible.

This new-century edition has been especially revised in the sections devoted to general anatomy and embryology. "Gray's Anatomy" has always been noted for its practical character and in this matter also special effort seems to have been made to keep it up-to-date. With its 1,250 pages of text, the book is undoubtedly the best work for consultation on the part of the student or the general practitioner. Notwithstanding the special effort made by teachers and compilers of anatomical works in the last few years it is doubtful if any of the recent text-books are as complete, as generally useful, or as thoroughly satisfactory as old "Gray." In its new dress it will prove as helpful to a new generation as it has to several preceding generations. The illustrations are especially well done and the book is gotten up in characteristically good shape by the publishers who have for so many years known how to keep it abreast of the times.

Proceedings of the Ninth Annual Meeting of Military Surgeons of the United States, May 13, June 1 and 2, 1900.

This admirable volume is unusually rich, since it contains many of the doings by land and sea, in Cuba and the Philippines. Many of the long articles are too technical for interpretation by the ordinary surgeon, but even these, in many cases, are so graphically illustrated with charts and other devices as to place their otherwise cumbersome data within the range of the ordinary ken. Of the shorter articles perhaps the most strikingly original is that by Captain Guy Godfrey. In a few lines he explains a practical method of controlling hemorrhage in the arm and axilla which needs no ligature and no apparatus. The method is to raise the arm upward, backward, and inward as far as possible; when the limit of motion is reached the pulse can no longer be felt in the axilla. If it is desired to keep the arm in this position for safety or for operation a clove hitch is taken around the waist with an ordinary roller bandage and tied under the opposite axilla. The posture works better in muscular men than in stout or slender men. Godfrey believes that the circulation is obstructed by the mass of muscle pressing the axillary artery against the clavicle when that artery is bent over the bone.

Another interesting series of observations by Captain Miles Standish and Major J. M. Banister on the standard of vision which should be required of enlisted men in the Army and on the extent to which military surgeons should be educated in ophthalmological lines are particularly well timed, because of a similar agitation which is now taking place in the British service.

In Captain C. W. Borden's paper on military surgery the interesting conclusion is reached that "as many deaths upon the battlefield may be expected from the

use of the modern small-caliber rifle as from the older firearms." The lateral destructive effect of the high-velocity bullet is well seen in compact bones, in organs with fluid contents, and in organs containing large quantities of intercellular fluid. At a range of under six hundred yards the presence or absence of fluid in the stomach, bladder, etc., makes all the difference between penetrating and almost harmless wounds and the entire destruction of the viscus. In fine, the ninth volume of these Transactions is a banner contribution and one which every surgeon will be glad to have upon his book-shelves.

Surgical Technic. A Text-Book on Operative Surgery. By Fr. Von Esmarch, M.D., Professor of Surgery at the University of Kiel and Surgeon General of the German Army, and E. Kowalzig, M.D., late First Assistant of the University of Kiel. Translated by Professor Ludwig H. Grau, Ph.D., formerly of Leland Stanford, Jr., University, and William N. Sullivan. M.D., formerly Assistant Surgeon of U.S.S. "Corwin." Edited by Nicholas Senn, M.D., Professor of Surgery at Rush Medical College, Chicago. The Macmillan Company, New York and London.

One of the chief merits of this book is indicated in that clause of the title page which states the number of illustrations contained in its pages. Their presence in such abundance is explained by a knowledge of the fact that the whole work was originally produced in competition for a prize offered by the German Empress for the best handbook of surgical technic, and it was the author's idea to present his material as much as possible by the graphic method. In his own words, "a glance at an illustration representing a dressing, an operation or an anatomical preparation, enables one to recall to memory most rapidly all former knowledge concerning the same." That this method of compressing an immense amount of information into a comparatively small number of pages is a suitable one which in this instance is adequately exploited is evidenced not only by the award of the prize to the author, but by the universal adoption of the book as a standard by his countrymen, and we are therefore to be congratulated upon the fact that its pages have been made accessible to us as well.

The descriptions are everywhere short and to the point, carrying out the motto on the title page "Kurz and Bündig," and, beginning with general considerations on asepsis, preparation of instruments, ligatures, dressing materials, etc., the treatment of clean and infected wounds, bandaging and narcosis take up the regional surgery of the entire body, excepting gynecological operations, and furnish a very excellent commentary on the illustrations. For the most part these, too, are very good, but there are some glaring exceptions which spoil the otherwise admirable appearance of the book. Such are, for example, those on pages 762 and 772 intended to depict the lithotomy and Trendelenburg positions, respectively, but which are so absurd in conception and execution as to be positively ludicrous, while crudity of execution is particularly conspicuous among many of the cuts devoted to operations on the head. The mechanism of the appliance termed "*irrigateur à vide bouteille*" is rather difficult to comprehend until one realizes that, as pictured on page 21, it is upside down and then the mystery of water flowing up hill is explained. Taken as a whole the chapter on splints is perhaps the most satisfactorily illustrated, though the many ingenious and complicated contrivances shown have to a great extent lost their point now that the tendency is to rely almost wholly on plaster of Paris under the control of the X-ray in the treatment of fractures.

One omission that is surprising in a German book is the absence of any mention in the section on antiseptics of Crédé's work on the bactericidal action of silver in soluble and metallic form. For the most part the work of foreign operators receives adequate consideration and many Americans, McBurney, Fowler, Senn, Halsted and O'Dwyer, are mentioned, though the operation to which the latter's name is attached is dismissed in a paragraph stating that, owing to the large number of instruments and constant supervision it requires, it has as yet found but little favor in Germany.

Taken all in all the book combines so many admirable qualities that editor, translators and publishers have done us a service in presenting it, and our thanks are due to each of them. In view of the difficulties of such a task criticism hardly seems fair, yet a little more time and care expended in the translation would have produced a text infinitely more pleasant to read and free from such errors as that Doyen's angiotribe produces a pressure of 2,000 *kilometers* (p. 247) and that an intravenous infusion of salt solution should be allowed to enter the vessel at the rate of 10 cubic centimeters a second (p. 280).

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Maladies de la Voix. Par André Castex. 8vo, 312 pages. Illustrated. C. Naud, Paris.

Short Talks with Young Mothers on the Management of Infants and Young Children. By Dr. Charles Gilmore Kerley. 12mo, 262 pages. G. P. Putnam's Sons, New York and London.

The Practical Medicine Series of Year-Books. Vol. III. Eye, Ear, Nose and Throat. Edited by Drs. Casey H. Wood, A. H. Andrews, T. M. Hardie. 12mo, 340 pages. Illustrated. The Year-Book Publishers, Chicago.

A Manual of Ophthalmoscopy for Students and General Practitioners. By Dr. J. E. Jennings. 8vo, 180 pages. P. Blakiston's Son & Co., Philadelphia.

Report of the Commissioner of Education for the Year, 1899-1900. 2 Vols. Government Printing Office, Washington.

On Disorders of Assimilation, Digestion, etc. By Sir Lauder Brunton. 8vo, 495 pages. Illustrated. The Macmillan Company, New York.

The Standard Medical Directory of North America for 1902. Quarto. 924 pages. G. P. Engelhard & Company, Chicago.

The Accessory Sinuses of the Nose. By Dr. A. Logan Turner. 8vo, 211 pages. Illustrated. Longmans, Green & Co., New York.

Diseases of the Intestines. By John C. Hemmeter. Vol. I, 8vo, 742 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

The Practical Medicine Series of Year-Books. Vol. III. 12mo, 346 pages. Illustrated. The Year-Book Publishers, Chicago.

The Elements of Physical Chemistry. By Harry C. Jones. 8vo, 565 pages. The Macmillan Company, New York.

Transactions of the American Orthopedic Association. Fifteenth Session. Vol. XIV. Philadelphia.

ORIGINAL ARTICLES.

THE PRESENT STATUS OF SERUMTHERAPY IN TYPHOID FEVER.[1]

BY JAMES EWING, A.M., M.D.,
OF NEW YORK;
PROFESSOR OF PATHOLOGY IN CORNELL UNIVERSITY MEDICAL COLLEGE.

IN view of the very successful results that have been obtained by the serum treatment of diphtheria and the preventive therapeutics of rabies, the question naturally arises as to why no great success has followed very numerous attempts to affect favorably the course of typhoid fever by serumtherapy. On many grounds a comparison of the clinical features and pathological characters of diphtheria and typhoid fever would seem to indicate the latter disease rather than the former as the one more favorable for the successful inauguration of a system of serumtherapy.

Diphtheria is a disease which commonly develops with great rapidity and without announcing its advent by distinct premonitory symptoms. Its focal lesion in the pharynx often reaches extensive development in a few hours; its toxins are thrown into the circulation in overwhelming doses and produce grave cellular alterations in vital tissues in the first stages of the malady. Typhoid fever, on the other hand, is slowly ushered in, as a rule, by several days of premonitory symptoms or mild illness, serious anatomical lesions are not present till the second or third week, ample time is offered before either the intestine is gravely damaged or the internal viscera exhibit degenerative changes for the administration of any agent that may have power to inhibit the growth of the bacillus typhosus or to neutralize its toxins. Yet the mortality of diphtheria has been greatly reduced by specific antitoxin treatment, while typhoid fever has long remained untouched and almost unapproached by advances in the knowledge of artificial immunization.

It may be of interest to point out some of the reasons which may be advanced to explain this failure to solve the problem of successful serotherapy of typhoid fever. In the first place it develops more clearly each year that there are fundamental differences in the nature of these two bacterial diseases which were long overlooked. In diphtheria the bacteria multiply rapidly on superficial mucous surfaces and seldom reach the general circulation, producing their effects by diffusible toxins absorbed from the focus of infection. Successful isolation of the bacillus diphtheriæ from the circulating blood is of rare occurrence, and the few cases in which it has been accomplished serve only to demonstrate the almost invariable rule that in fatal diphtheria the blood is free from the specific bacterium of the disease.

In typhoid fever, while earlier and several recent studies by Pasquale, Thiemich, Kraus, Ettlinger, Stern, James and Tuttle, Neuhaus, Fränkel, and Klein, indicated that the blood seldom yields positive culture of bacillus typhosus, very recent reports from several sources prove that with more careful technic the bacillus can be isolated from the blood in the majority of cases, even comparatively early in the disease. This conclusion has for some time been favored by the increasing proportion of successful attempts to obtain the bacillus from the cutaneous lesions. Thus, Soudakoff and Thiemich obtained the bacillus in fifty per cent. of their cases from the rose spots, and more recently Neuhaus obtained it from the skin in thirteen of fourteen cases.

Regarding the occurrence of the bacillus in the blood Kraus and Kuhnau showed that there is a type of typhoid septicemia in which the microorganism is practically always to be isolated from the blood. During the past year several studies have shown that even in routine cases a much higher proportion of successful results may be obtained than had been regarded as possible. Thus Castellani was successful in twelve of fourteen cases. Schotmuller has contributed an important study of sixty-eight cases in eighty-five per cent. of which he found the bacillus in the blood. He distributed twenty c.c. of blood from the basilic vein in several flasks containing from 200 to 300 c.c. of broth, the dilution nullifying the bactericidal action of the blood, while the large bulk of blood tended to insure a successful result if any bacteria were present. This result emphasizes the absolute necessity of drawing conclusions in this field only from the use of considerable quantities of blood. Almost equally successful were Auerbach and Unger, who planted only from ten to thirty drops of blood in 300 c.c. flasks of bouillon. Examining the broth in hanging drops they sometimes found at first a very scanty growth of non-motile rods or threads which, when replanted on fresh broth free from blood, gave an abundant growth. With these small quantities of blood they had seven positive results in ten cases.

These studies and others of similar import which are known to be in progress prove that typhoid fever in the great majority of cases, whether fatal or favorable, is a form of septicemia; and, as many features of the disease have led us to suspect that the symptoms of typhoid fever are not referable so much to the intestinal lesions as to the presence of the bacteria in the blood and viscera, the increasing frequency of reports of typhoid infection without intestinal lesions thus becomes quite intelligible.

[1] Read before the New York County Medical Association, Nov. 18, 1901.

Typhoid fever therefore is largely a bacteremia, while diphtheria is a toxemia.

Another important addition to the knowledge of typhoid fever has resulted from recent bacteriological studies of the blood and the investigation of the agglutinative properties of the serum, which tend to show that there is a wide variation in the characters of the bacteria concerned in the disease. Babes was among the first to point out various marked differences between cultures of bacillus typhosus isolated from typhoid cadavers. Some of them produced gas and indol, properties which tended to throw them into the colon group. He usually obtained from the same cadavers cultures of typical typhosus, and, while denying emphatically that the irregular types were capable of producing typhoid fever, he admitted that they probably influenced the character of the disease, since they acted in animals just as did typhosus. Many observers have reported extreme differences of virulence in cultures obtained from typhoid cadavers. Remy finds that when typhosus is grown along with colon bacillus the former loses its susceptibility to agglutination and may be so far altered as to be unidentifiable by any or all of our present means.

On the other hand, studies of the colon bacillus have shown that this species very frequently develops characters which render its separation from typhosus extremely difficult. Sternberg isolated several species of coli from water which failed to produce indol or gas or to coagulate milk, but were agglutinated by high dilutions (1-10,000) of typhoid serum. Decleman also obtained colon cultures which produced no gas and did not coagulate milk. Remy finds that when grown with typhosus the colon bacillus regularly loses its capacity to produce gas and indol. Jatta found that he was able to isolate from diarrheal stools at different periods of the disease different types of coli which varied in their capacity to coagulate milk and were agglutinated in varying degrees by blood serum.

The hope that the agglutination test would prove a ready means of separating typhosus from the colon bacillus has not been realized. Stern found that typhoid serum may agglutinate coli even more strongly than typhosus, especially colon cultures from the stools of the typhoid patients whose serum was employed in the test. Widal and Nobecourt found a patient whose serum agglutinated typhosus only in 1-20 dilution, but clumped a culture of coli from an abscess in a dilution of 1-12,000. Eight days later the serum had no effect on typhosus while retaining its power over the colon bacillus. Beco concluded that typhoid serum agglutinates most colon cultures, sometimes very actively but always less strongly than typhosus, if an extremely powerful serum be used.

This conclusion, while generally holding, has found exception in the experience of Widal, Sternberg, Remy and Jatta. Moreover, Jatta showed that this high agglutinating power of typhoid serum over the colon bacillus could not be referred to secondary infection by the bacillus coli, since it was present in the serum of animals receiving injection of typhosus only. Not only has the agglutination test failed to distinguish typhosus from coli, but it appears to be unable to separate all cultures of these germs from other more distantly related members of the intestinal flora, since it has been shown by Gruber, Durham, Sternberg, Deelman, Remy, and many others, that typhoid serum even in comparatively high dilutions may agglutinate Gaertner's bacillus enteritidis, Nocard's bacillus psittacosis, and Petruschky's bacillus fecale alcaligenes.

The accumulating evidence of studies in these related fields seems therefore to justify Durham's division of this entire group of intestinal bacteria into three, instead of two, classes, and to warrant the common application of the term "Gaertner's group" to those species intermediate between typhosus and coli, with which the production of gas and indol and the coagulation of milk, while often present in traces, are too uncertain to warrant their acceptance either as genuine typhosus or as genuine coli. An important practical bearing of these conclusions was not apparent until bacteriological studies of the blood of typhoid fever began to show that the typical symptoms of this disease may be associated with the presence in the blood, as the undoubted etiological agent, of bacteria which produce gas and indol, coagulate milk, and are not agglutinated by typhoid serum.

The credit of having first drawn definite attention to the fact that some irregular forms of typhoid fever are referable to infections by bacteria intermediate in type between Eberth's bacillus and the colon bacillus belongs originally to several French observers who combined the results of study of the bacteria isolated from the stools and the agglutinating properties of the serum of these patients. Achard and Bensaude appear to have published the first complete description of a case of this type in 1896.

In 1897 Widal isolated from an abscess in a phthisical patient a bacillus resembling coli, but producing no indol and not fermenting lactose, while the patient's serum, which had no effect on typhosus or on cultures of genuine coli, agglutinated this bacillus in dilution of 1-1,000. In 1898, Gwyn isolated from the circulating blood of a case of typhoid fever a bacillus which produced no indol and did not ferment lactose, but fermented glucose, while the patient's serum, inert with typhosus, agglutinated this bacillus in 1-200 dilution. Shortly before this Brill had described an epidemic of typhoid fever of a type which probably belonged in this class, since in none of the eighteen patients was Widal's reaction obtained. Unfortunately there were no bacteriological analyses of the blood, while cultures of the stools yielded the colon bacillus. More recently Schotmuller, in five of sixty-eight routine cases of typhoid fever, found bacteria in the circulating blood which on biological characters must be classed as intermediate between bacillus

typhosus and bacillus coli. These cases were usually of mild type and not such as might be expected to show bacteremia. The blood sera failed to agglutinate cultures of genuine typhosus, but acted strongly on the bacillus obtained from the blood in each case, and all of five sera agglutinated all the cultures in the series. In about the same proportion of cases, five out of sixty-two, studied by Kurth, the diagnosis of paratyphoid inflection was made, either by the presence of specific agglutinating properties in the serum, or from the isolation from the stools, or urine, of bacteria which produced no indol, fermented glucose, and in other characters resembled Gaertner's group. These cultures lost their virulence when heated to 60° C. and were harmless when administered by mouth to guinea-pigs and rats. The serum of these patients had no effect upon bacillus typhosus nor on bacillus enteritidis, but actively agglutinated the particular cultures isolated from the stools.

Rodet recently isolated from three typhoid cadavers bacilli which produced no indol and no gas, but grew on potato like the colon bacillus. The initial cultures were indifferent to both typhoid and colon serum, but subcultures were agglutinated by both sera in high dilutions, most actively by the colon serum. Animal inoculations gave a serum which actively agglutinated typhosus. These apparently contradictory results belong to the class on which is based Roux's theory that the colon and typhoid bacilli are identical species with varying and interchangeable physiological properties. The exact characters exhibited by one representative of the paracolon group of bacteria, isolated from a case of post-typhoidal osteomyelitis, have been very minutely studied by Cushing.

The above observations indicate clearly the importance of recognizing the paracolon or Gaertner group of intestinal bacteria as rather frequent excitants of diseases which may be clinically indistinguishable from typhoid fever. They serve to explain the failures of Widal's reaction which are constantly being reported, and they point out the necessity for testing suspected typhoid serum both on genuine typhosus and on cultures of this paracolon group as well.

We have thus far shown that typhoid fever differs from diphtheria, first, in being a septicemia rather that a toxemia; and, second, in that the bacterial agent in the disease, not to mention secondary infections, may show wide variations in its biological characters and in the quality of the agglutinating substance which it causes to be elaborated in the system. Moreover, the toxic products of bacillus typhosus differ radically in their clinical qualities from diphtheria toxin, while their relation to the symptomatology of the disease is very uncertain. Typhotoxin differs from diphtheria toxalbumin in being slowly soluble in water, hence resembling globulin rather than serum albumin. It differs from globulin, moreover, in being very slowly soluble in NaCl. According to Martin it does not possess the digestive properties of diphtheria toxin. Typhotoxin kills rabbits and guinea-pigs very slowly; diphtheria toxin kills them very rapidly (Breiger, Fränkel). In neither animal does it give symptoms of lesions similar to those of typhoid fever, even when acting energetically; yet Remlinger produced rather typical lesions of typhoid fever in rats and rabbits by feeding them on cabbage-leaves soaked in cultures of bacillus typhosus. Peyer's patches were swollen, there were ulcers in the colon and the spleen and lymph-nodes were hyperplastic. Recently, Walker induced typical lesions of typhoid fever in rabbits by combining succesive inoculations of typhoid cultures with immune horse serum and serum extract. Sanarelli grew typhosus in broth for a month in the thermostat, then for eight months at room temperature, finally killing and macerating the bodies of the bacilli at 60° C. for some days; 1.5 c.c. of this extract per 100 grams of guinea-pig killed in twenty-four hours, with bloody diarrhea and lesions which showed a very slight tendency of the toxin to pick out lymphatic structures, but with no specific lesions in Peyer's patches. Martin found the filtrate of virulent cultures to kill animals with subnormal temperatures, but with no specific lesions. Bodies of the bacilli killed by chloroform were much more toxic, but even then did not specially affect Peyer's patches. Bacillus enteritidis gave somewhat similar results.

We may conclude, therefore, that the bodies of typhoid bacilli contain poisons which do not diffuse rapidly in fluids as does diphtheria toxin and which are incapable of producing the specific lesions of typhoid fever. Not only has no specific typhotoxin been isolated from test-tube cultures of bacillus typhosus or from the cadavers of typhoid patients, but Chantemesse and Widal, Gruber and Durham, and many others, have shown that the procedures which render animals immune to infection by the typhoid bacillus are incapable of protecting them against infections of the products and macerated bodies of these bacteria.

The problem of the serumtherapy of the disease is therefore the preparation of a serum which is principally bactericidal and not antitoxic as in diphtheria. It was at first believed that the agglutinating substance represented the essential principle in preventive sera in typhoid fever, but it has gradually become clear that, while the agglutinins are usually abundant in strongly protective sera, such active sera may exhibit very little agglutinating power. Pfeiffer has shown that cholera serum may lose almost all its agglutinating properties while retaining a high degree of protective power. Deutsch, among others, has made very careful observations on the development of agglutinins and of protective substances in the blood of inoculated animals, finding that the two curves are generally but not always parallel, and never superposable. He concluded that all strongly agglutinating sera are also strongly protective, but that highly protective sera may contain little agglutinin.

Although immune serum usually contains both bodies at the same time and loses both in about equal proportions when heated or inoculated with typhoid germs (Gruber and Trumpp), by a comparison of the agglutinating powers of many sera, Pfeiffer and Kolle, Fränkel and Otto, and Deutsch have concluded that these properties have no necessary relation to each other, and certainly do not reside in identical substances. Their conclusion accords with the fact that the highly protective diphtheria and tetanus sera are not agglutinative, while the agglutinating typhoid and cholera sera cannot be made to show highly protective qualities.

Again, several studies have shown that agglutination depends to a large extent upon the characters and condition of the bacteria themselves and is only partly determined by the quality of serum with which they are treated. Johnson found that actively growing cultures of typhosus often tend to agglutinate spontaneously, while slowly growing attenuated cultures do not. Durham found that of sixteen different vibrios the less virulent races were much more susceptible to agglutinins produced by virulent cultures than were those virulent races themselves. Walker's observations seem to show conclusively that typhoid cultures showing greater tendency to spontaneous agglutination and agglutinating more strongly in immune serum are the less virulent cultures. The most that can be claimed is that the agglutination is not the essential feature of protective serum, that agglutination depends very often upon special tendencies of the bacterial species rather than upon the presence of much bactericidal substance in the serum, but that agglutinative power is, however, in the majority of cases, a fairly reliable index of the protective power of a serum.

Serumtherapy in typhoid fever therefore demands the preparation of a principle which is not largely antitoxic, which indeed is not to be measured by its agglutinative powers, but one which responds to the far more critical test of protection by a mechanism which has thus far largely escaped recognition. This means probably that it must be both antitoxic and bactericidal. The evidence that both these properties are demanded may be gathered from the results, on the one hand, of Brieger, Kitasato, Wassermann, Beumer, Peiper, Sirotinin, Bitter, and Bruschetini, all of whom prepared protective sera which were more or less antitoxic, and, on the other hand, of Pfeiffer and Kolle, Funk and Bockenham, and Sanarelli, whose actively protective sera were slightly or not at all antitoxic.

We may now consider briefly what steps have been taken with or without regard to the foregoing principles and what success has been achieved in the preparation of a protective serum for typhoid fever in the human subject. Bockenham inoculated horses, first with the filtrate of typhoid cultures, then with the killed cultures, and then with both alternately, thus securing a serum of considerable bactericidal power and with active protective and curative powers in animals. Pope and Cowen tested this serum on the human subject in a few cases with results which seemed to them more favorable than those secured by any other plan of treatment of the disease. Immediate improvement followed each injection and the course of the fever appeared to be distinctly shortended. Bockenham's serum was prepared, however, without special regard to some theoretical requirements. The first of the theoretical difficulties was recognized by the endeavor to produce a polyvalent serum, *i.e.*, one that would protect against a considerable variety of races, each with special characters, which, as has been shown, may be concerned in the disease. Each of these races seems to require an extremely specialized bactericidal agent and some may be little affected by a serum which rapidly destroys other races of bacillus typhosus. This difficulty was foreshadowed by the conflicting results of Widal's test, the serum of some convalescent patients failing entirely to agglutinate particular cultures of typhosus, at least partly because the serum did not contain the special agglutinin for that culture, although probably quite capable of agglutinating a bacillus which came from the patient's own intestinal tract.

This idea of the necessity of a polyvalent serum was first suggested by Bockenham in connection with the manufacture of antistreptococcus sera. The idea was followed up systematically by Tavel and Walker, who inoculated horses for a period of from one to three years with several species of bacillus typhosus, finding that the specialism in the immunizing bodies required to protect is very marked and that greater specialism is demanded as the protective qualities increase. These results probably indicate the real difficulty in the prepation of practically effective sera for the human subject. Although Walker secured enormous agglutinative powers in his horses (1-2,500,000), this power was exhibited only against the particular culture longest employed in the inoculations. Against other cultures its agglutinative qualities were far less and proportional to the length of treatment by each culture. Tavel tested serum drawn after one year's treatment of horses, on typhoid patients, finding that it abolished the plateau stage of pyrexia, the fever falling by lysis and the patients making rapid recovery. Other cases treated by two-year serum are soon to be reported, and three-year polyvalent serum is now being tested (Walker).

A second practical step in advance followed the recognition that the protective substances are not equally distributed in the body. Johnson and McTaggert found that the whole blood possesses more agglutinins than the serum. Wassermann (1899) tested the protective qualities of extracts of the different organs and concluded that the typhoid antibodies are produced in the spleen; but almost at the same time Roth's studies in a similar line led to negative conclusions. Jatta's studies indicated that within from two to three days after inoculation the agglutinins

of the spleen exceed those of the blood serum, but later the serum is always the stronger. He did not test the protective qualities of the spleen and his results were amplified by Castellani, who found that while the serum contains more agglutinins the spleen has more protective bodies.

Deutsch took up the matter in a systematic and exhaustive manner. He found that the spleen and marrow usually show greater bactericidal power than the blood serum, which he attributed to the abundance of leucocytes in these organs. Yet in splenectomized animals bactericidal properties developed as in the normal animals, indicating that the function of the spleen may be fully assumed by other tissues. Bactericidal substances made their appearance on the fourth or fifth day of infection, simultaneously with the disappearance of leucocytes from the peritoneum, the site of inoculation. Removal of the spleen on the third day greatly reduced the animals' chances of recovery apparently through the removal of already formed bactericidal substances. The lymphatic organs contained less agglutinin than the serum. Agglutinins developed perfectly in splenectomized animals, but splenectomy on the third to fifth day of infection sometimes prevented their formation. He found marked discordance between the bactericidal and agglutinating properties of the spleen, and hence concluded that these properties reside in different substances. Deutsch made the interesting discovery that lung tissue in the early stages of infection has from ten to twenty times as powerful agglutinating action as the serum. Later, the difference was not so great. Normal lung was also found to be from ten to twenty times as active as normal serum of guinea-pigs.

These researches of Wassermann and Deutsch represent the acme of progress in the investigation of immunity in typhoid fever, and they culminate, as have many previous studies, with strong indications that immunizing bodies are the product chiefly of the colorless blood and lymph-cells. Daubler's partly contrary results in this field, however, here deserve mention, since this investigator found that during the process of immunization against typhoid infection the leucocytes and purulent exudates do not increase in bactericidal properties, but remain the same throughout.

The above results have to some extent received a practical test on the human subject in the attempt of Jez to influence typhoid fever by injections of visceral extracts from infected animals. Proceeding from the principle that the normal central nervous tissue possesses both preventive and curative properties in tetanus, Jez tried extracts in glycerin, alcohol, salt, broth, and water, of the liver, spleen, lymph-nodes, thymus, marrow, brain and cord, of healthy rabbits, administering them subcutaneously and by mouth, but without effect on typhoid infection of rabbits. He then inoculated rabbits with 10 c.c. of typhoid culture, the animals dying on the fourth day. Extracts in alcohol and water of the thymus, spleen, marrow, brain, and cord proved actively preventive, when 10 c.c. were injected with 10 c.c. of culture. An extract of the above tissue made with alcohol, water, salt, and glycerin, to which a trace of carbolic acid and pepsin was added (details not given), had no bactericidal action in the test-tube and gave no Widal reaction; but when given hypodermically is said to have had a surprising effect upon the course of typhoid fever in eighteen cases on which it was tried. The fever was reduced, pulse improved, sweats induced, and the general nervous condition much improved. Glucksmann failed, however, to obtain any curative action from Jez's extract on typhoid infection in rabbits, and Walker, replacing Jez's extractive solution with curative horse serum, failed to find any greater curative powers than were obtained from horse-serum alone. Jez's results lack, perhaps, the scientific certification of the work of Tavel and Walker, but represent a line of work in the right direction.

Another independent line of investigation has been caried on by Chantemesse in Paris, from which especially successful results have been expected, inasmuch as this investigator claimed, in 1898, to have devised a method capable of furnishing extremely active and specific typhotoxin. Chantemesse cultivated the bacillus upon the filtrate of an emulsion of splenic tissue digested with pepsin, carefully avoiding access of air during the manipulations. The fluid thus secured was found to be extremely toxic, especially for horses, but on exposure to air rapidly lost its poisonous properties. Horses were very susceptible to minute doses for at least one year, after which they developed increasing immunity and their blood serum became strongly bactericidal and both curative and preventive for animals. The results of the treatment of 100 cases of typhoid fever with Chantemesse's serum have recently been reported. The total mortality was 6 per cent., which is not better than the results obtained in many such series of cases treated by ordinary methods. Yet two patients began treatment on the twenty-first and twenty-fifth days when already suffering from pneumonia with a pulse-rate of 140. A third case was that of a very fat woman who could not be bathed; she died of a large bedsore present on admission. Three of the patients died of perforation, against which the treatment seemed of little avail. On the other hand, all patients treated before the tenth day recovered. The serum usually caused a rapid and steady defervescence. Or the temperature rose again, the relapse being more severe than the original fever, but a second injection caused a rapid lysis of fever. The injection of the serum invariably caused a pronounced improvement in the general symptoms, as attested by all the clinicians who observed the course of Chantemesse's treatment in the Paris hospitals.

It remains for investigators who possess experience and extensive equipment to combine and extend the results already obtained in the two aforementioned fields and to determine what

success can be secured in the treatment of typhoid fever by injections of serum and visceral extracts from animals which have been treated with a view to producing polyvalent immunizing bodies. It would appear that the outlook in this field is fairly indicative of success, if not in the preparation of a curative serum for typhoid fever, then at least in essential progress in the knowledge of artificial immunization both in this disease and in other infections which have heretofore baffled all attempts at serumtherapy.

SURGICAL COMPLICATIONS OF TYPHOID FEVER.

BY ROBERT ABBE, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO ST. LUKE'S HOSPITAL.

It would be strange, indeed, if the very complicated human body were swarming with untold myriads of disease-producing bacilli of typhoid fever and no trace were left of surgical complications. Judging from my own experience in past years, the physician, as such, is apt to regard this disease as rightly relegated to the domain of medical practice; so that it is profitable for a few moments to review the surgical conditions which are occasionally seen in connection with or sequent upon the few weeks of fever.

An analogous series of complications may be found in other infections, such as that of tubercle, and we can see why much the same causes bring about similar complications. The study of one aids us to understand the other. A more perfect research of tubercle infection has been made far in advance of any other, because it is a more readily demonstrable bacillus, its life course is slower and the experimental research more satisfactory. But one fact derived from the research of tubercle infection can be mentioned at this point to elucidate corresponding facts in the subject we are to discuss. It has been demonstrated that when tuberculous fever is induced in animals and a local injury (such as fracture of a bone, injury of a joint, or local irritation of an internal part) takes place, there is a local demonstration of the disease. The same is true of pyogenic coccus infections. We have but to enumerate the varied surgical troubles incident to typhoid fever and we see at once the relation of cause and effect—the colonizing of bacilli at the site of injury. This point should be ever present in the mind of the physician.

To begin with, let us notice the bone abscesses which most practitioners have encountered in the late weeks of occasional typhoid cases. They have been seen in almost every bone of the body, but the relative frequency with which they occur in such parts as are subject to bruises is so far an argument of their causation that one is struck by the fact. The tibia, which by its exposed position is most subject to injury (or what the Germans call "insults"), is most often the seat of abscess. Taken altogether the bones of the lower extremities are oftener affected than all others of the body, as 112 to 104, according to Keen, while, considering the bones nearest the surface, compared with those buried under muscle or within the body, we find the contrast is 180 to 51.

Enough is thus in evidence to show that a slight accidental injury to the patient will often determine a swarming of the prevalent bacteria to the part, which the weak resistance of the tissues fails to conquer, and an abscess results. In most of these a culture of the pus reveals a pure culture of the typhoid bacillus, but in others a mixed staphylococcus and typhoid, and in some a pure staphylococcus. This latter demonstration is consistent with the complicated toxemia of mixed infections from ulcerated Peyerian patches and other sources. The same abscess development is seen in the course of muscles and shows a low grade of inflammation. In the synovial sheaths of the tendons and in joints there is frequently initiated a synovitis from which, however, the infecting bacillus quickly disappears and the irritation is almost sure to quiet down, very rarely leaving fibrous ankylosis or pus, and only in the hip-joint producing mechanical trouble. Here, strangely enough, there are many cases on record of synovial distention with luxation of the femur which has remained permanent after the

convalescence which keeps the patient so long on his back that the trouble is overlooked.

The next most important and destructive deposition of bacillus colonies is in the laryngeal cartilages. Study of this shows that in the later weeks of convalescence there is, not rarely, a tumefaction of the internal laryngeal mucous membrane from abscess, due to destructive necrosis of the cricoid cartilage or of the arytenoids. The other cartilages are very much less likely to be affected. The complication is extremely dangerous and fatal from suffocative action in over 75 per cent. of the cases not operated upon; in those in which tracheotomy has been done, even including extreme cases, the mortality has been reduced to about 50 per cent.

It is only too often demonstrated that, when hoarseness and beginning obstruction are noticed, the rapidity of the edema is so marked that tracheotomy is a matter of emergency. The quick consideration of the importance of hoarseness in this fever and the safeguarding of the patient by tracheotomy is to be borne in mind.

One of the most common and distressing complications of typhoid is femoral phlebitis. While this is not rare in any septic infection, it is not uncommon for it to be followed in succeeding years by large varicose veins which become a surgical charge. Indeed, it has been frequently of so severe a grade that blockade of the iliacs and gangrene of the leg have often been seen. This latter mishap has also been many times demonstrated to follow endarteritis of the popliteal, tibial and femoral in typhoid fever.

There may be no demonstrable determining factor in causing a deposition of colonies of migrating bacilli, but the probability is that the sluggish current of blood in the lower extremities allows their growth without other cause. It has been shown that the endarteritis is equally seen in the right or left foot, producing gangrene, while the phlebitis of typhoid attacks the left femoral vein four times as often as the right. This is explained by Keen by the anatomical fact of the left common iliac vein passing below the right common iliac artery and thus receiving unequal pressure. Though these extreme varicosities of the left superficial veins even extend to the femoral and pubic, they can be safely and permanently relieved by operation without endangering the life of the foot, as I have had occasion to demonstrate.

As in other septic affections, we see parotitis not infrequently in typhoid; indeed the sympathy between the parotid gland and ulcerative lesions of the abdominal viscera was noted thirty years ago by Paget, and one must regard it as a conspicuous target for many forms of septic infection. In most cases it subsides without surgical treatment, and, for fear of the easily produced parotid fistula, I think the indurated parotid swellings suspected of harboring pus should never be incised until pus has been demonstrated by time or aspiration.

We come now to speak of the most interesting phase of typhoid surgery, peritonitis from perforating ulcers of the intestine.

Before we consider that, however, I cannot forbear noting the frequent call for consultation to differentiate between appendicitis in its milder forms and the early pain in the appendical region in typhoid. Undoubtedly the two closely resemble each other, but a waiting policy clears all doubt away, and as the dictum of a few years ago, that "the time to operate on appendicitis is when you recognize it," has passed, the mild symptoms do not call up profound anxiety as of old.

Perforation of the intestine in typhoid always takes place in the area of the ulcerated Peyerian patch and invades the peritoneal coat not oftener than once in a hundred cases. It is of the utmost interest and importance to know whether preliminary symptoms of extreme ulceration ever show in a tender point a local crepitus. If so, one might anticipate disastrous perforation by ice application and opium. From cases I have seen in both typhoid and gastric ulcer, in which a fine crepitus of limited area coincident with a point of tenderness were recovered from, I have in my mind no question that impending perforation may be cured by Nature, but this is difficult to demonstrate.

Having had occasion to operate for peritonitis after perforating typhoid ulcers in five patients, it is of interest to draw the picture of the surface of the bowel, as it appears at operation—for few who simply treat the medical case as such can realize it. When the intestine which harbors the diseased patches which have not ulcerated is passed between the fingers, the general thickness of the gut is not exaggerated, nor is its peritoneal surface inflamed or highly congested except when suppurative peritonitis has been set up; but the patch itself can be felt thickened. In some cases several patches near the one which had perforated were covered by a blanket of greenish lymph —nearly corresponding to the area of the Peyerian patch—while the neighboring surface was simply inflamed and smeared with foul fluid. Between the coils were scanty flakes of exudate and free yellow fluid as in any septic peritonitis—with the further appearance of yellow typhoid stool and gas. The gas which continually escaped from the moment of perforation distributed itself among the bowels, but did not separate the liver from the costal pleura. This was conclusively shown in one case; yet I have seen free gas in the peritoneum when ulcer of the stomach or of the duodenum had perforated, which did separate the liver from the ribs so that the hand could be laid flat in the space. The presence of the apron of omentum accounts for this difference, which I have not heretofore seen noted.

After perforation has existed some hours there will be found one or two pints of yellow fluid in the pelvis and lumbar fossæ. The opening in the small bowel will always be seen to be in the center of a gangrenous patch within fifteen or twenty inches of the caput coli, so that it can be

quickly found. On an average it is large enough to admit the end of a lead pencil, and at every peristaltic movement, or in handling, gas and yellow fluid bubble out. Thus we have a picture of what has been going on from the moment of perforation to the moment of operation. If, now, we can imagine that at the first a slight leakage occurs, instead of a sudden explosive discharge of gas and fluid, it is entirely conceivable that a speedy exudate would be thrown about the spot and the abscess would be walled in. There is little doubt that this has happened, as Fitz has shown in a very small number of cases which seem to have shown the history of perforation and made spontaneous recovery. We feel that if such slow beginning were recognizable, it would be possible to help Nature by administering quickly sufficient morphine to paralyze all peristaltic action, keeping the patient absolutely quiet and applying ice over the lower abdomen. This is consistent with the best treatment of peritonitis from appendix perforation, which has been well epitomized by Ochsner, when he says that almost all acute attacks can be controlled by "ice, opium and starvation" for three days. But unfortunately explosion is more common than leakage in typhoid perforation, and hence acute tearing pain is the first evidence of trouble.

The pain comes usually in the third or fourth week, when the disease is running a comfortable course or convalescence has begun. Shock followed by a temperature of 105° or 106° F. supervenes, and rapid increase in leucocytosis is seen. In spite of the depleted condition of the patient, Nature makes a heroic effort to overcome the new trouble, and we see almost as good a quality of reparative lymph in the abdominal peritoneum as in cases of corresponding gravity, stricken down in otherwise fine health from other intra-abdominal injury.

Statistics show that most recoveries from operation for perforation have come from delaying until shock has passed, and twelve hours after is regarded as the most favorable period. If operation can be done under favorable circumstances within twelve to eighteen hours the recoveries rise to 32 per cent. and fall again to 13 per cent. for operation after twenty-four hours.

The operative care of perforative peritonitis is now laid out on such well defined lines that I need not mention it here. One addition has been made to the surgery of the subject by Finney's suggestion that at the earliest suspicion a competent surgeon should be requested to make a small exploratory opening of the abdomen under cocaine anesthesia, which is harmless to the patient, if nothing serious is found, and is the only infallible way of knowing if extravasation has occurred. If this principle of action be carried out in all our hospitals—as it may easily be—we shall soon add greatly to creditable reports.

My own five cases show one recovery. Two were in soldiers of the Spanish War, half moribund with typhomalarial infection when the perforation occurred; both died. The other would have been, I think, a typically good patient, taken in the third week with violent pain and vomiting. In an hour and a half his temperature was 106° F. The patient was out of town and perforation was suspected, but I was not summoned until more than twenty-four hours had passed. Operation was done twenty-seven hours after perforation, but a big opening fifteen inches from the colon was found and liberal extravasation had occurred. A dozen oval areas of greenish protective lymph marked the site of inflamed patches, but one had become gangrenous and given way. Quick and thorough operation was tried, though he had an almost hopeless aspect when it was done. The opening in the bowel was stitched in the wound with a tube held in by a pursestring suture inverting the opening about it, so as to drain off gas and fluid from the distended and paralyzed intestine; but the patient had already been so far infected that he lived less than a day after operation. The fifth case was a duplicate of this in an exhausted patient. Operation was done thirteen hours after perforation. The latter was enlarged and anastomosed with sutures to a nearby portion of bowel. The anastomosis worked well, but the patient was too exhausted by typhoid and survived only three days.

The brief time allotted in which to speak of the physical aspects of this disease has prevented my touching on many other complications: but enough has been said to stimulate every man to be alert to these possibilities and to emphasize the pleasant assurance that surgery is coping with the most desperate of them when a timely union of medical and surgical forces is permitted.

13 West 50 Street.

THE DETECTION OF TYPHOID BACILLI IN THE FECES AS A DIAGNOSTIC TEST OF TYPHOID FEVER, AND A COMPARISON OF THIS TEST WITH THE WIDAL REACTION.[1]

BY HENRY A. HIGLEY, M.D.,
OF BROOKLYN, N. Y.

While most cases of typhoid fever can be diagnosed sooner or later by clinical symptoms alone, it is nevertheless a fact that in many instances purely clinical observations do not lead to a diagnosis until valuable time has been lost both in the institution of the treatment and in the sanitation of this disease. The value of the Widal test has of late considerably fallen in general estimation. This I believe to be due to the indiscriminate application of this test to both typical and atypical forms of typhoid fever and, furthermore, to the faulty technic frequently employed in making the test. Since due consideration has been given the later phase of the subject in a recent communication (Medical News, Jan. 11, 1902) it is not my intention to further discuss it here.

Nearly two years ago I began a series of ob-

[1] A Study from the Department of Pathology of the College of Physicians and Surgeons, Columbia University, New York.

servations in order to ascertain the frequency with which the Bacillus typhosus could be isolated from the feces of typhoid patients and to determine the value of such isolation tests in the routine diagnosis of the disease. In order to confirm the clinical diagnosis and for purposes of comparison Widal tests were also carried out in nearly every case. Only those cases are here reported in which I had the opportunity of personally observing the patient until the termination of the disease or until the diagnosis of typhoid fever was positively made.

Technic.—In the Widal tests fresh fluid blood serum was used, the requisite dilutions being made with a capillary pipette.

The method used in isolating typhoid bacilli from the feces was that recommended by Hiss (*Jour. Exper. Medicine*, 1897, Vol. II., No. 6). This method involves the use of a "plating" medium, in which an emulsion of the feces is "plated" in the regulation manner, and of a "tube" medium into which "stab" inoculations are made from the colonies developing in the plating medium after from twelve to eighteen hours' growth at 37° C. If typhoid bacilli be present they develop in the plating medium into characteristic thread-forming colonies which can be readily differentiated from the colonies formed by other bacteria found in feces, such as colon bacilli, etc. In the tube medium typhoid bacilli give rise to a uniform cloudiness without the production of gas, while colon and allied bacilli do not cloud the medium uniformly but always give rise to gas. The typhoid bacilli are therefore isolated by means of the plating medium and further identified by means of the tube medium. In the later portion of this work the original plating medium recommended by Hiss was replaced by another which has recently been devised by Dr. Hiss and which was personally communicated to me by him and thoroughly tested in my routine diagnostic work. This medium is composed of agar, 15 grams, gelatin, 15 grams, sodium chloride, 5 grams, glucose, 10 grams, and water, 1,000 cubic centimeters. The results obtained by the use of this new medium fully equal, if indeed they do not exceed, those given by the original medium. It is certain that it favors the development of a larger number of colonies than does the old medium and thus renders the detection of typhoid bacilli more probable when they are present in small numbers in the feces. Furthermore, its preparation is very simple, no titration or correction of reaction being necessary. In addition to the characteristic reactions given by the bacilli in the Hiss plating and tube media, every typhoid bacillus so isolated was further tested to determine its agglutinating capability.

Epitome of Cases.

Case I.—W. H., aged fourteen years. The prodromal history was characteristic of typhoid fever. No epistaxis. The case was first seen on what was probably the third clinical day. Evening temperature 101.3° F.; pulse 92. Widal reaction negative. An endeavor to isolate the typhoid bacillus[1] from the feces taken on the following (the fourth) day was unsuccessful. No further Widal or "isolation tests" were attempted until the eighth day of the disease, when, with the Widal reaction still negative, typhoid bacilli were isolated from the feces. Very few typical colonies were seen in the plating medium. The characteristic typhoid roseola appeared on the ninth clinical day. Widal reaction on tenth clinical day negative. No Widal attempted on eleventh clinical day. Widal reaction (1-20) positive on twelfth clinical day. Typhoid bacilli were never isolated from the urine, although attempts were made on the eighteenth, twenty-fourth, twenty-sixth and thirty-sixth clinical days.

Case II.—M. B., aged eighteen years. Typical prodromal history of typhoid fever. First seen on what was probably the eighth clinical day. Evening temperature 103.1° F.; pulse 101. Widal reaction (1-30) positive. "Isolation test" negative. Daily "isolation test" negative until the twelfth clinical day, when typhoid bacilli were found in large numbers. No characteristic typhoid eruption was ever observed. Typhoid bacilli were never isolated from the urine, although attempts were made on the twenty-fifth, thirtieth and forty-first clinical days.

Case III.—A. W., aged twenty-seven years. No prodromal history. Onset sudden. First seen on what was probably the third clinical day. Evening temperature 103.4° F.; pulse 109. Chill during the afternoon. Widal reaction and "isolation test" on the fourth clinical day; both negative. No Widal or "isolation tests" until the tenth clinical day, when the Widal test (1-50) was positive, but the "isolation test" still negative. Characteristic typhoid eruption was never observed. Typhoid bacilli were never isolated from the feces, although attempts were made on the twelfth, eighteenth, twenty-sixth and thirty-fourth clinical days. Typhoid bacilli were never obtained from the urine, although attempts were made on the twenty-sixth and thirty-fourth clinical days. The disease ran a typical typhoid course and the reaction persisted (1-50) into convalescence.

Case IV.—C. H., aged twenty years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the eighth clinical day. Morning temperature 101.2° F.; pulse 89. Widal reaction negative. "Isolation test" positive. Many typical colonies were seen in the plating medium. Characteristic typhoid eruption appeared on the ninth clinical day. A positive Widal reaction was never obtained, although attempts were made on the tenth, sixteenth, twenty-first, twenty-ninth and thirty-seventh clinical days. The first attempt to obtain typhoid bacilli from the urine was made on the twenty-fifth clinical day. It was successful. Urine contained albumin and hyaline casts.

Case V.—A. H., aged nine years. Character-

[1] For the sake of brevity the attempts to isolate typhoid bacilli from the feces will hereafter be referred to as "isolation tests."

istic prodromal typhoid history with epistaxis. First seen on what was probably the seventh clinical day. Evening temperature 102° F.; pulse 97. Widal reaction and "isolation test" on eighth clinical day; both negative. Widal and "isolation test" were not attempted until the tenth clinical day, when the "isolation test" was positive and the Widal negative. Widal test next attempted on the thirteenth clinical day and found positive (1-30). Characteristic typhoid eruption was never observed. No attempt was made to isolate typhoid bacilli from the urine until the twenty-third clinical day, when the organisms were found. Urine contained albumin, but no casts.

Case VI.—C. W., aged fifteen years. Fairly characteristic prodromal typhoid history. First seen on what was probably the fourteenth clinical day. Evening temperature 104.3° F.; pulse 112. Widal reaction negative. "Isolation test" positive. Characteristic typhoid eruption had not been previously and was not subsequently observed. Further Widal tests were not attempted. No attempt was made to obtain typhoid bacilli from the urine.

Case VII.—E. M., aged twenty-two years. Characteristic prodromal typhoid history. No epistaxis. First seen on what was probably the fifth clinical day. Evening temperature 102.2° F.; pulse 100. Widal reaction and "isolation test" on sixth clinical day; both negative. Characteristic typhoid eruption appeared on the seventh clinical day. Widal reaction and "isolation test" on the seventh clinical day were still negative. "Isolation test" was next tried on tenth clinical day; positive. Widal still negative. Widal test was next tried on twelfth clinical day; positive (1-30). Typhoid bacilli were never isolated from the urine, although attempts were made on the twenty-eighth, thirtieth, thirty-second and thirty-eighth clinical days.

Case VIII.—O. H., aged twelve years. Characteristic prodromal typhoid history. No epistaxis. First seen on what was probably the tenth clinical day. Evening temperature 103.3° F.; pulse 106. "Isolation test" positive. Widal reaction negative. Widal reaction was next tried on the twelfth clinical day; negative. Widal reaction was next tried on fifteenth clinical day; positive (1-50). Characteristic typhoid eruption was never observed. First attempt to isolate typhoid bacilli from the urine made on the fifteenth clinical day; negative. Next attempt on the twentieth clinical day; positive. Urine contained albumin and hyaline and granular casts.

Case IX.—E. S., aged nineteen years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the seventh clinical day. Evening temperature 103° F.; pulse 89. Widal reaction (1-10) positive. "Isolation test negative." Characteristic typhoid eruption appeared on the ninth clinical day. "Isolation test" was next tried on the fourteenth clinical day; positive. Typhoid bacilli were never obtained from the urine, although attempts were made on the twenty-first and thirty-first clinical days.

Case X.—F. W., aged eighteen years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the twelfth clinical day. Evening temperature 103.5° F.; pulse 110. Widal reaction negative. "Isolation test" positive. Widal reaction was next tried on the nineteenth clinical day; positive (1-20). Characteristic typhoid eruption was never observed. First attempt to isolate typhoid bacilli from urine was made on thirty-third clinical day; positive. Urine contained albumin and hyaline casts.

Case XI.—H. A., aged twenty-five years. Characteristic prodromal typhoid history with epistaxis. First seen on what was probably the eighteenth clinical day. Evening temperature 104.1° F.; pulse 112. Widal reaction (1-50) positive. "Isolation test" negative. "Isolation test" was tried on the twenty-first clinical day; positive. Characteristic typhoid eruption was never observed. No attempt was made to isolate typhoid bacilli from the urine.

Case XII.—D. M., aged six years. Indefinite prodronial typhoid history. No epistaxis. First seen on what was probably the seventh clinical day. Evening temperature 104.3° F.; pulse 125. Widal reaction and "isolation test" negative. Characteristic typhoid eruption appeared on the eighth clinical day. Widal reaction was next tried on the twelfth clinical day; positive (1-30). "Isolation test" still negative. "Isolation test" was next tried on the fourteenth clinical day; positive. First attempt to isolate typhoid bacilli from the urine was on the twenty-second clinical day; result, positive. Urine contained albumin, but no casts.

Case XIII.—J. B., aged thirty-four years. Characteristic prodromal typhoid history. No epistaxis. First seen on what was probably the tenth clinical day. Evening temperature 103.3° F.; pulse 102. Widal reaction (1-20) positive. "Isolation test" negative, but positive on the next (the eleventh) day. No typhoid bacilli were ever obtained although attempts were made on the eighteenth and twenty-eighth clinical days.

Case XIV.—W. F., aged twelve years. Characteristic prodromal typhoid history. No epistaxis. First seen on what was probably the seventh clinical day. Evening temperature 102.6° F.; pulse 101. Widal reaction and "isolation test" both negative. "Isolation test" positive on the following (the eighth) day. Widal reaction still negative. Widal reaction was next tried on the twelfth clinical day; positive (1-30). Characteristic typhoid eruption appeared on the ninth clinical day. Typhoid bacilli were never isolated from the urine, although attempts were made on the twentieth, twenty-seventh, thirty-seventh and forty-seventh clinical days.

Case XV.—B. A., aged twenty-two years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the seventeenth clinical day. Evening temperature 105° F.; pulse 110. Widal reaction negative. "Isolation

test" positive. Characteristic typhoid eruption was never observed. Further Widal tests were not made. Attempts were not made to obtain typhoid bacilli from the urine.

Case XVI.—H. B., aged eighteen years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the fifth clinical day. Evening temperature 102.8° F.; pulse 89. Widal reaction and "isolation test" negative. Widal reaction was next tried on the seventh clinical day; positive (1-50). "Isolation test" still negative. "Isolation test" was next tried on the twelfth clinical day; positive. Characteristic typhoid eruption appeared on the tenth clinical day. Typhoid bacilli were never obtained from the urine, although attempts were made on the twentieth and twenty-eighth clinical days.

Case XVII.—C. M., aged fourteen years. Fairly characteristic prodromal typhoid history. No epistaxis. First seen on what was probably the seventh clinical day. Evening temperature 102.3° F.; pulse 99. Widal reaction and "isolation test" negative. Characteristic typhoid eruption appeared on the following (the eighth) day. "Isolation test" was next tried on the eleventh clinical day; positive. Widal reaction still negative. Widal reaction was next tried on the sixteenth clinical day; positive (1-20). Typhoid bacilli were never obtained from the urine, although attempts were made on the twenty-fifth and thirty-fifth clinical days.

Case XVIII.—P. F., aged twenty-nine years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the seventeenth clinical day. Evening temperature 105.2° F.; pulse 114. Widal reaction (1-50) positive. "Isolation test" positive. Characteristic typhoid eruption was never observed. Attempts to isolate typhoid bacilli from the urine were made on the twentieth and twenty-sixth clinical days. First attempt negative; second positive. Urine contained albumin, but no casts.

Case XIX.—S. R., aged ten years. No prodromal history. Onset sudden. First seen on what was probably the fifth clinical day. Evening temperature 101.2° F.; pulse 104. Widal reaction and "isolation test" both negative. "Isolation test" was next tried on the eighth clinical day; positive. Widal reaction still negative. Characteristic typhoid eruption appeared on the ninth clinical day. Widal reaction was next tried on the twelfth clinical day: positive (1-50). First attempt to isolate typhoid bacilli from the urine was made on the nineteenth clinical day. Result, positive. Urine contained albumin and hyaline casts.

Case XX.—O. W., aged eighteen years. Indefinite prodromal typhoid history. No epistaxis. First seen on what was probably the seventh clinical day. Evening temperature 102.3° F.; pulse 95. Widal reaction and "isolation test" negative. "Isolation test" positive on the following (the eighth) day. Widal reaction negative. Widal reaction still negative on the twelfth clinical day. Widal reaction was next tried on the fourteenth clinical day; positive (1-20). Characteristic typhoid eruption appeared on eighth clinical day. Typhoid bacilli were never obtained from the urine, although attempts were made on the twentieth and thirty-fifth clinical days.

Case XXI.—D. P., aged seven years. Fairly characteristic prodromal typhoid history. No epistaxis. First seen on what was probably the fifth clinical day. Evening temperature 101.3° F.; pulse 108. Widal reaction and "isolation test" negative. "Isolation test" positive on the following (the sixth) clinical day. Widal reaction negative. Widal reaction was next tried on the eighth clinical day; positive (1-50). Characteristic typhoid eruption was never observed. A complicating measles developed on the ninth clinical day. First attempt to isolate typhoid bacilli from the urine was made on the thirty-second clinical day. Result, positive. Urine contained albumin and hyaline casts. [This case will be subsequently reported in detail.]

Summary.—A review of these twenty-one cases shows that typhoid bacilli were isolated from the feces in twenty, while a positive Widal was obtained in only eighteen.

In making a comparison of the diagnostic value of the "isolation test" and the Widal reaction it is necessary to withdraw from consideration certain of these cases. Case XVIII. should be withdrawn entirely because it was not seen sufficiently early to test the value of either procedure. In considering the "isolation test" Case XV. should be withdrawn for the same reason. In considering the Widal reaction Cases VI. and XV. should be withdrawn, since only one Widal test was made in each; Case X. because the interval between the first and second attempts to obtain this reaction was too long; also Case XI. because it was not seen sufficiently early in the course of the disease.

With these cases eliminated we find that in eighteen cases in which the "isolation test" was successful the average day of isolation was the tenth, while in fifteen cases in which a positive Widal reaction was elicited the average day of its first appearance was the twelfth.

Comparing these procedures from another standpoint we find that in seventeen cases typhoid bacilli were isolated from the feces during the second week of the disease, while in only twelve was a positive Widal obtained before the fourteenth day.

If we compare them from still another and final point of view we find that the earliest day of successful isolation was the sixth and the latest the twenty-first (leaving out of consideration Case XV.), while the earliest appearance of a positive Widal was on the sixth day and its latest primary appearance on the eighteenth day.

It is furthermore apparent from a study of these cases that both of these procedures, when used in combination, make possible the establishment of a diagnosis of typhoid fever in many instances before this could be accomplished by purely clinical observations. In only three, Cases

VII., XII., and XVII., of the twenty-one did the appearance of the characteristic typhoid eruption render the diagnosis positive before it had been established by one of these methods.

In eighteen of the cases attempts were made to isolate typhoid bacilli from the urine. In eight this was accomplished. The earliest day of such isolation was the nineteenth and the latest the thirty-third. In every case in which the bacilli were so obtained albumin was present in the urine

Conclusions.

1. During the second week of typhoid fever, when technical aids are of the greatest value to the practitioner, isolation of typhoid bacilli from the feces gives slightly better results than does the Widal test. These two methods used in combination, when the tests are carefully and persistently made, render material aid in the diagnosis of this disease previous to the appearance of distinctive clinical symptoms.

2. By the use of the Hiss isolation method, especially with the substitution of the new plating medium, the detection and isolation of typhoid bacilli are, to one familiar with bacteriological methods, simple, reliable and practical.

In conclusion it gives me pleasure to express my obligation to Prof. T. Mitchell Prudden and Dr. Philip Hanson Hiss, Jr., for assistance and suggestions during this work.

REMARKS UPON SOME EXPERIENCES WITH THE WIDAL REACTION.[1]

BY E. LIBMAN, M.D.,
OF NEW YORK;
ASSISTANT PATHOLOGIST, MOUNT SINAI HOSPITAL.

In the remarks which I am about to make in response to your very kind invitation, I shall confine myself almost entirely to my personal experience in performing the Widal tests for the various services of the Mount Sinai Hospital from March 1, 1898, to October 15, 1901. These tests, 3,514 in all, made by myself or by the members of the house-staff under my supervision, were all carried out according to the same method. It was always my good fortune to be kept well informed upon the clinical aspects of the cases through the kindness of the successive house-physicians. The uniformity of the work makes the series a valuable one and will, I hope, afford me the opportunity of bringing out some points of interest, although I am well aware that I shall deal mainly with facts that are a part of our general knowledge.

The method used by me admits of quite accurate dilution. It has been detailed in an article in the Mount Sinai Hospital Reports, Volume I., and I shall therefore not describe it fully here. Certain data will, however, be of interest.

Dried blood was used for all our tests, except as mentioned later. The blood was always used within four hours after it had been obtained, often directly after it had dried. It is distinctively disadvantageous to use the blood before it has dried, because the corpuscles interfere with the clearness of the reaction. If the blood is allowed to stand too long before being utilized, for instance, over night, the results are not entirely satisfactory.

The cultures of the typhoid bacillus were prepared as follows: A stock culture on agar was kept from which daily inoculations into bouillon were made. The agar culture is inoculated about every three weeks upon serum-glucose-agar.[1] From this it is inoculated upon agar. The growth on the serum-glucose-agar is often not very marked, but after re-inoculation on the agar-tube a very profuse active growth is obtained. By the use of this method the organism has been kept growing very vigorously for over two years. A potato-tube can be used instead of the serum medium, but the results are not as uniform nor as good.

The bouillon used had an acidity varying from 1 to 1.5 per cent. (phenolphthalein used in titrations). We have usually obtained better growths when Merck's peptone was used in making the medium than when Witte's peptone was employed. As a rule 1 per cent. peptone was used. The bouillon cultures were incubated at a temperature of 32°-35° C. In summer they were not put into the thermostat. The temperature of 35° C. is more favorable than 37° C., because the bacilli are much more motile at that temperature, and we have obtained the best results with the most active organisms. On this point observers have differed very much. The bouillon cultures are used about eighteen to twenty-four hours after inoculation. We have generally used a dilution of 1 to 20. If the reaction proved positive with this dilution in cases that were not typical instances of typhoid fever, the reaction was repeated in a dilution of 1 to 50. The later reactions were all positive.

In some instances in which the cases presented none of the usual symptoms of typhoid fever, except the febrile state, we succeeded in obtaining reactions in dilutions of 1 to 200 or 1 to 300. Such instances will be cited later. The reactions were viewed directly after being made and a large number were immediately positive. The cultures were then allowed to stand twenty minutes on the laboratory table and again examined. No longer time limit was used. We have been very particular in regard to diagnosing positive reactions. We considered a reaction positive when all motility had ceased and when the bacteria were gathered into clumps. A few non-motile bacteria between the clumps do not deter us from calling a reaction positive, nor would one or two motile bacteria in the field.

The process of clumping has been so often described that it is unnecessary to go into the details here. It must be noted, however, that the clumps are very characteristic, and, after a little practice, should not be confounded with clumps that are not due to the specific action of the blood.

[1] Read by invitation before the German Medical Society, November 4, 1901.

[1] For mode of preparation see Libman, Journal of Medical Research, Volume I.

The clump looks like a network, the individual bacilli being distinct; some look bright and some dark. Often all the bacilli in the clump may move and even the whole clump may appear to do so, but so long as there are only a few bacilli between the clumps, and these few are not motile, the reacion must be considered positive.

Since 1899 we have reported only positive reactions, everything else being called negative. It is very risky to speak of "partial reactions" or "suspicious reactions" or "incomplete reactions," etc. These so-called "partial reactions" occur in many diseases. We have noted them often in cases of tuberculosis, and particularly in generalized tuberculosis, the very condition most difficult to differentiate from typhoid fever. I came near having a sad experience in such a case in 1898. A man was admitted to the service of Dr. Manges with a history of headache, constipation, malaise and fever. After arriving at the hospital his fever gradually rose, as it does in typhoid fever, and he developed a roseola on the abdomen. The spleen was enlarged to percussion, but not felt. On several occasions I reported the Widal reaction as being partial. At times I was inclined to call it positive, but the clumps were always indistinct and there were rather too many nonmotile bacilli between. A week after admission he developed ptosis and internal strabismus of the right eye and the further course was typical of tuberculous meningitis. The lumbar puncture fluid when inoculated into a guinea-pig caused marked tuberculous lesions, and the postmortem examination of the case revealed a general miliary tuberculosis.

The reactions in our cases were made every day until a positive reaction was obtained, or until it was made evident that the given case was not one of typhoid fever. When the reaction was persistently negative in a case strongly suspected of being typhoid fever, tests were made with serum obtained by raising a blister. The latter tests were all negative. Most observers, however, have found that serum gives about 10 per cent. more positive reactions than does the dried blood.

Altogether 3,514 tests were made in 860 cases. Of these 334 were cases of typhoid fever. They are distributed as follows: 1898, 233 cases, 855 tests; 1899, 185 cases, 1,030 tests; 1900, 242 cases, 922 tests; 1901, 200 cases, 707 tests.

It will be noted that in 1899 more tests were made and fewer cases examined than in any other year. This was not a matter of chance. It was due to the fact that during most of that year the cultures were incubated at too high a temperature, and we had to test oftener till we obtained positive reactions. In compiling some of the statistics, I have therefore omitted the data belonging to that year.

The results in the cases of typhoid were as follows: 1898, 98 cases positive, 5 negative; 1899, 61 cases positive, 9 negative; 1900, 104 cases positive, 4 negative; 1901, 69 cases positive, 3 negative; total, 334 cases positive, 21 negative.

In percentages the figures are: 1898, 5.1 per cent. negative; 1899, 12.8 per cent. negative; 1900, 3.7 per cent. negative; 1901, 4.16 per cent. negative; total, 5.9 per cent. negative.

The reason for the high figure in 1899 has been given. The totals for 1900 and 1901 give a more reliable figure as they were nearly always made with cultures incubated at 35° C. They include 173 positive cases and 7 negative—in other words, 3.9 per cent. of the cases never gave a positive reaction.

These results agree pretty well with those given by most authors. Thus, Cabot[1] has collected 5,978 cases, 2.8 per cent. of which never gave a reaction, and Kneass and Stengel[2] give a negative percentage of 4.8 per cent. These figures cannot be considered accurate, as they represent the statistics given by a large number of workers using different methods and varying decidedly in their ideas of what constitutes a positive reaction. However, to the practitioner it makes no difference whether 1 per cent. or 10 per cent. of typhoid fever cases give no reaction, because, no matter how few fail to give a reaction, any case he meets may be one of those that never respond to the test.

In the 526 cases that were not instances of typhoid fever *we never obtained a positive reaction*, although the blood of these patients was in many instances repeatedly examined. These cases included all the usual forms of febrile disease. Most writers report instances of the occurrence of a positive Widal reaction in other diseases than typhoid fever. Cabot's collected statistics give 5 per cent. in 5,668 cases, and in 113 cases the blood was examined only once. Kneass and Stengel put the figure at 2 per cent. We are inclined to ascribe many of these positive results to three causes: (1) As Cabot suggests, some were due to errors in technic or judgment. (2) Some of the cases were instances of typhoid fever which clinically resembled other diseases, and in which the observer did not properly examine the case for evidences of typhoid fever. (3) Some were due to previous attacks of typhoid fever.

In trying to give figures as to the day upon which the reaction became positive, we are met by the great difficulty of determining the first day of the disease, which is notoriously uncertain in typhoid fever. Frequently we were even dealing with a relapse, although the patient did not give the history of any previous illness.

In the following statistics I have included only those cases in which the patient gave a history of having been taken sick on a certain day. Only 263 cases could be utilized for the figures. The results for each year expressed in percentages are as follows:

	1898.	'99.	1900.	'01.	
At end of first week	4.55	.0	7.5	10.0	per cent. positive
At end of second week	36.0	21.0	34.0	44.7	" " "
By the 20th day	59.0	42.0	66.0	74.5	" " "
By the 30th day	88.4	92.1	77.0	96.0	" " "

The following table, which relates to those

[1] Serum Diagnosis, 1899.
[2] American Year Book of Medicine and Surgery, 1898.

cases only in which a positive reaction occurred after the blood had failed to give a reaction affords more reliable data.

At end of first week	5.7	per cent. positive
At end of second week	36.	" " "
By the 20th day	67.	" " "
By the 30th day	92.	" " "

The earliest reaction was one found on the third day. This was a case of typhoid fever in a boy nine years of age. The blood gave a positive reaction the first time it was examined. Probably the case was of longer duration than it was supposed to be.

The latest day on which a reaction first appeared was the sixty-seventh.

There were found positive: On the fifth day, 3 cases; on the sixth day, 2 cases; on the seventh day, 3 cases; on the eighth day, 4 cases; on the ninth day, 5 cases; on the tenth day, 5 cases; on the eleventh to fifteenth day, 36 cases.

Only one-third of the cases gave a positive reaction by the end of the second week and two-thirds by the end of the third week. This is the main disadvantage of the Widal reaction. There is, however, a brighter side to these statistics. Many cases of typhoid fever come to the physician for treatment after the illness has lasted a week or more. The important question is, therefore, how soon after the cases are seen do they give a positive reaction? We cannot answer this from data obtained in private practice. We must, therefore, have recourse to the hospital data, and it must be noted that patients arriving in a hospital have, for the most part, been suffering a longer time than those that seek aid from the family physician. The figures at my disposal show that in a series of 295 cases 50 per cent. gave a positive reaction within the first two days after admission; 80 per cent. by the end of the first week, and 90 per cent. by the end of the second week.

The data given above include a number of children varying in age from one and one-half to fourteen years.

Dr. Gershel of the house-staff has recently published an article on the value of the Widal reaction in children[1] and I shall confine myself to a few quotations from his paper.

His observations extend over 84 cases of the disease. Three of the cases never gave a positive reaction. In 115 cases of other febrile diseases a positive reaction was never found. Gershel found that the main facts concerning the reaction were the same in children as in adults, but that the reaction is of greater value in the former, because typhoid fever is more atypical in them and also more difficult of diagnosis. The reaction appeared quite early in some cases that at first presented no distinct symptoms of typhoid fever. On the whole the reaction appeared earlier than in adults. For a description of some very interesting cases of typhoid fever in children resembling pneumonia or meningitis I would refer to Gershel's paper.

[1] Medical Record, November 23, 1901.

Before giving you the conclusions to be drawn from the material I have laid before you, I shall, for the sake of completeness, rapidly cover a few points of interest concerning the reaction. The reaction, in a number of cases, first appeared during convalescence or during a first or second relapse. Sometimes a reaction would disappear and return after a few days, or during the relapse. The reaction was of no use in the prognosis, occurring late in some mild cases and early in some severe ones. This is almost the universal experience. As to the persistence of the reaction, practically no researches were made. In a number of cases, however, it was noted that it disappeared after a few days. In one case, recently observed, a reaction was obtained in a typical case on the day of admission, and not thereafter. This fact is of importance as it probably explains the absence of the reaction in some cases of typhoid fever while under observation.

Many data concerning the persistence of the reaction are given by Cabot. Some of these I shall cite. Widal found the reaction to persist for one year, at least, in 11 out of 40 cases. He also found the reaction positive in one case eight years after the disease, in one case twenty-six years, in one case nine years, in one seven years, and in one eight years. Elsberg examined the blood of six patients who had had typhoid fever one-half to ten years previously and obtained negative results. Biggs and Park found the reaction persist to a marked extent for three or four months only. On the other hand, Grünbaum claims to have found a positive reaction in a patient thirty-seven years after the attack of typhoid fever.

Although these facts force us to acknowledge that the occurrence of a positive reaction in any fever case, if the reaction be the first one made, may be attributable to a previous attack of typhoid fever, we have not encountered any trouble therefrom. Among our many cases which were clinically not typhoid, we never obtained a positive reaction even in those instances in which there was a definite previous history of typhoid fever.

Recently, a patient who had suffered from typhoid fever two years previously at the Boston City Hospital, a positive reaction bein obtained at that time, was admitted with symptoms suggestive of the disease. On the day of admission no reaction was obtained. On the following day it was positive. The occurrence of the negative reaction before the positive one demonstrated conclusively that the man was again suffering from typhoid fever. However, in cases in which the reaction is positive at the first examination it is important to question the patient carefully as to the possibility of a former attack of typhoid fever, unless the clinical picture is sufficiently characteristic to dispel all doubts.

General Deductions.

1. A positive Widal reaction, according to our experience, always means that typhoid fever is or has been present.

2. Partial reactions are absolutely to be ignored.

3. A negative reaction does not exclude the existence of typhoid fever. It occurs under any of the following conditions: (*a*) The reaction has already disappeared; (*b*) the reaction may only appear later; (*c*) the culture may be at fault; (*d*) the case is clinically one of typhoid fever, and there may never be a positive reaction; (*e*) the disease is not typhoid fever. A negative reaction may occur if the patient is suffering from an infection by a paracolon bacillus and still, for the practitioner, the case is identical with one of typhoid fever. Again, a positive reaction may occur when the case is clinically not one of typhoid fever, and yet the autopsy, if there be one, may show the presence of the typhoid bacillus in some part of the body, or it may be found *intra vitam* in the urine, feces, rose spots, blood, or some complicating lesion.

4. Scientifically, the Widal reaction is of the greatest value in establishing the presence of infection by the typhoid organism in cases such as those last referred to and in assisting in identifying the typhoid bacillus.

Practically, it is also of great use, but it is not so valuable as we would wish it to be. Often the diagnosis of typhoid fever is very clear long before we obtain the reaction. In many cases, however, it alone can establish the diagnosis. This is particularly true of the atypical cases in which pneumonic or meningeal symptoms usher in the disease. These cases are more common in children than in adults. We have had the good fortune to obtain positive reactions quite early in many of the atypical cases. The citation of a few cases in this connection will be of interest.

Case I.—Described by Dr. Alfred Meyer in the Mount Sinai Hospital Reports, Volume I. A man, aged forty-four years, was admitted on October 1, 1898, with a history of insomnia and headache lasting one month, loss of flesh and strength. On admission he was found to talk in a rambling fashion; there was slight ptosis of the left eyelid; the tongue deviated somewhat to the right; there was an occasional tremor of the right side of the face and tongue; the voice was tremulous; marked tache cérébrale present; temperature 101.8° F.; pulse 126; respiration 30; physical examination negative. His temperature ran daily between 99 or 100 to 102 or 103° F. On October 7th a Widal test proved negative; temperature 99.2 to 101.2° F. On the 8th it was positive in a dilution of 1 to 50; on the 9th it was again positive. The temperature remained about the same for a number of days and then declined until it became normal on October 25th. All of the symptoms disappeared. At no time was any enlargement of the spleen or a roseola found.

Case II.—Service of Dr. Brill. A nurse suffered from fever, headache and malaise for two days. The spleen could not be distinctly felt; no roseola . After three days' stay in the hospital the temperature became normal. The case appeared to be one of auto-intoxication. The Widal reaction was negative until two days after the temperature became normal. Three days later it was evident that the reaction had not misled us, as the patient again had fever and the next day suffered from severe pain in the splenic region, increased fever and rapid pulse. The spleen was palpable. It seemed very probable that we were dealing with a relapse accompanied by splenic infarction. The temperature and pulse remained high for a number of days, but the subsequent history is not known because the patient returned to her home while still ill.

Case III.—A girl, fifteen years of age, was admitted to the service of Dr. Manges in April, 1898, with the history of several hemorrhages from the bowel on the previous day. There was no distinct previous history. The spleen was found slightly enlarged, the temperature was normal. A Widal reaction was positive up to 1 to 100. The patient gradually recuperated and had fever for a number of days. She was discharged from the hospital, but returned about two weeks later with a relapse with typical symptoms.

Case IV.—A boy who presented symptoms of perforation of the bowels was operated upon by Dr. A. A. Berg.[1] His previous history was negative except for malaise of a few days' duration. On opening the abdomen a small perforation in the ileum was found and was sewn up. The boy had no roseola and no palpably enlarged spleen. His temperature remained moderately high for a few days only. Repeated blood examinations were made, and finally, a number of days after convalescence had been established, the reaction was found positive 1 to 100. This case occurred in the spring of the year, as did also Case III., as noted.

Case V.—A young man, eighteen years of age, was admitted with a history of two weeks' illness. He claimed to have had a chill every evening followed by fever. The spleen was very large and hard. His temperature in the hospital ranged for a few days between 100 in the morning to 103 or 104° F. at night, but he did not have any chills. There was no roseola and no plasmodia were found in the blood. Although a history and the hard spleen suggested malaria, a positive Widal reaction was found. To determine whether typhoid alone was present, or whether he might have a malarial attack at the end of a typhoid, no quinine was given. After a few days the temperature gradually fell to normal, and remained normal until he left the hospital.

Case VI.—The last case that I wish to describe is a particularly interesting one. A man of fifty years consulted me for an illness of four weeks' duration. In 1873 he had been sent to Denver for pulmonary tuberculosis from which he practically recovered. One year ago he had a hemoptysis after a slight exertion. The onset of the present illness was ascribed to taking a cold bath, which was followed by a chill. After this he coughed moderately and had a moderate amount of expectoration. He felt miserable all the time, but did not believe he had fever.

[1] Medical Record, June, 1901.

On examining the patient I found a large area of dulness at the right apex, with increased breathing, subcrepitant and coarse friction râles. The pulse was 120; the heart action poor. The spleen was enlarged to percussion and plainly felt below the free border of the ribs. It appeared to be quite soft. There was no history of malaria and no evidences of cirrhosis of the liver. I found a rectal temperature of 103° F.

Although aware of the fact that the splenic enlargement might be ascribed to a prolonged fever due to the pulmonary condition, I considered two other possibilities; first, that he was suffering from pulmonary tuberculosis *plus* typhoid fever; second, that I was dealing with a case of ambulatory typhoid fever and that the pulmonary signs represented an old, quiescent lesion. The first Widal reaction was negative; the second positive in a dilution of 1 to 100. No tubercle bacilli were found in the sputum. His temperature came down by lysis, taking eight days to reach the normal point. The splenic enlargement disappeared two days after I first saw him. There then appeared two suspicious spots on the back. The temperature remained normal for three weeks, when he had an attack of biliary colic followed by jaundice which still persists.

The final question is, When should the Widal test be made? In hospital work circumstances are such that the reaction can easily be made daily. In private practice this is hardly feasible. It is advisable, however, to test the blood for the reaction early in any fever case the diagnosis of which is in doubt. If the result be negative, as it is apt to be, a later positive reaction stamps the case as one of typhoid fever, and the reaction cannot be attributed to an earlier attack of the disease.

If a case present the classical symptoms of typhoid fever, it is not necessary to examine the blood, except possibly for two reasons: (1) If later in the course of the disease some perplexing symptom-complex arise, one can be sure that the original diagnosis was correct; (2) if some unusual observation is made, the case can be utilized for the purpose of advancing our knowledge of typhoid fever.

If the case be a doubtful one, the reaction should be made every two days until it becomes positive, or until in other ways a positive diagnosis of the condition has been established by the practitioner.

SOME OBSERVATIONS IN TYPHOID FEVER.[1]

BY FRANK SHERMAN MEARA, PH.B., M.D.,
OF NEW YORK.

I HAVE no desire to play the rival of the text-book nor do I wish to exercise overmuch my ingenuity at compilation, an art carried to no small degree of perfection, as analyses of addresses on such occasions and of contributions to an already redundant medical literature will demonstrate; but my purpose is, in the rôle of a humble practitioner, to set before you a few observations drawn from a class of cases the frequency of which makes you all interested participants and should provoke a fertile discussion based on your own experience; I refer to typhoid fever.

So ubiquitous is this disease that it commands universal attention, and so protean are its manifestations that were one conversant with all its bibliography, one, too, might be shunned as carrying the whole Bodleian library in his head. In all standard text-books and systems its description, measured quantitatively, dwarfs that of any other disease. Voluminous monographs have been devoted to it; tomes of no mean bulk have considered its complications, medical and surgical; treatises have been written on its bacteriology; endless articles have been devoted to its treatment, to say nothing of clinical reports, statistical analyses, and hygienic considerations, until even Shakespeariana seem put to shame beside it; and all this is fortunate, for few subjects are worthy of more careful treatment.

Fresh from the medical school and not yet with a hospital training I met my first case of typhoid fever in a country practice and—must I confess it?—promptly diagnosed it as malaria and treated it as such until, as the days wore on, the probability of the case dawned on me. The history was briefly as follows:

A youth, eighteen years of age, sent for me because he felt some malaise and appreciated the fact that he had some fever. He reported that he had taken cold three days before. His temperature for 103.8° F.; pulse, 80, and dicrotic. The physical examination was negative except for a reduplication of the second sound of the heart. His temperature gradually fell, showing a variation of about one degree between morning and evening for three weeks. All this time his pulse varied but little from normal, he was perfectly comfortable, but so drowsy as to be uncomplaining of his detention in bed. His appetite was excellent. The spleen could not be felt nor were spots seen at any time. An examination for plasmodia malariæ could not be made under the circumstances and the Widal test had not yet come into vogue. The continued temperature, not yielding to quinine, the slow, dicrotic pulse, the drowsy, comfortable condition of the patient and the absence of any obvious lesion responsible for the temperature leave no doubt of the diagnosis. How far this picture departed from the text-book type it is needless to remind you. I deem myself fortunate in having met this aberrant form thus early in my medical career, as it impressed on me the necessity of going outside of the types for diagnosis.

I had fallen into the most common error of diagnosis (in company, I grant you, not to be proud of) as the following statements will show. Thayer, in his "Lectures on Malarial Fevers," says: "It is a melancholy truth that a large body of medical men in this country have scarcely

[1] Read before the Riverside Practitioners' Society.

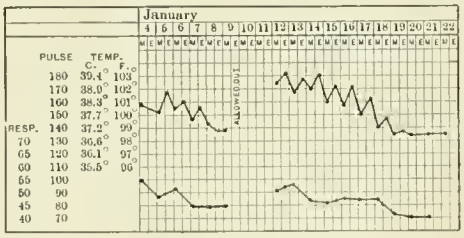
passed beyond the limits reached by Hippocrates in their clinical appreciation of the continued fevers." He shows from statistics that during six years preceding 1890 there were reported from New York city 2,060 deaths from malaria, 2,031 from typhoid; from Brooklyn 1,413 deaths from malaria, 1,002 from typhoid; from Baltimore 934 from malaria; 904 from typhoid, and shows that during this time in the Johns Hopkins Hospital there were forty-eight deaths from typhoid and only three from malaria. With these data, considering the mild type of malaria in the North, it is not difficult to appreciate the enormity of these errors in diagnosis.

The report of Dr. Victor C. Vaughan, a member of a board appointed by Surgeon-General Sternberg for the study of the cause and spread of typhoid among the troops during the war with Spain, affords interesting reading in this connection. The troops in the various camps were represented by medical men from widely-distributed localities and yet there was a striking unanimity in error. At Camp Alger they found most of the febrile cases diagnosed as malaria and yet hundreds of blood examinations which they instituted did not reveal one plasmodium. Their work among the numerous camps led them to the conclusion that "malaria was a very rare disease among those troops that remained in the United States." Among the twelve regiments of the first and third army corps there were 3,732 probable cases of typhoid, of which 1,584 were recognized by the army surgeons. In the early stages of these mild types a diagnosis can not be made off hand. Repeated examinations of the blood for the plasmodium and for the Widal reaction must be made to differentiate.

I was called in the summer of 1899 to see a physician who for ten days had had a mild type of fever which he himself considered malarial, but which was suspiciously resistant to quinine. When I saw him the morning temperature was 99.8° F., and the pulse 84. He had no rose spots and the spleen was not palpable. I carefully examined the blood for plasmodia, but without result. The diagnosis of malaria at first was fortified in his own mind by the fact that he came from New Jersey, though he was too shrewd a man to give much weight to the quondam Sherlock Holmes method of diagnosis of malaria from the character of the mud upon the patient's shoes. Time settled the diagnosis and he developed the signs of a mild typhoid which ran an uneventful course.

Another form of diagnosis that has come within my ken is typhomalaria. Some time ago I was called to a nearby city, to see a case in which this diagnosis had been made. The patient was a girl, fifteen years of age, who had returned two weeks before from Detroit with a fever which showed considerable excursion from morning to night. Her subjective symptoms were a chill five days before arriving home, fever, drowsiness and malaise. The diagnosis of malaria had been made and goodly quantities of quinine administered. In spite of this fact the temperature kept on the increase for ten days to two weeks and then began to abate a little. The patient was hungry and desired to sit up in bed; this she was allowed to do with the result that she had an intestinal hemorrhage. The next morning rose-colored spots were abundant and were noticed for the first time. The diagnosis was then changed to typhomalaria. I saw her on this day. It is needless to go into detail; I found a typical typhoid; spots, spleen, hemorrhage, temperature curve, all bespeaking the condition. No blood examination had been made.

A word about typhomalaria; if it mean anything, it means a mixed infection. How rare this mixed infection is can be appreciated by a perusal of Lyon's article in the Johns Hopkins Hospital Reports.[1] He was able to collect thirty cases which met the criteria demanded by scientific diagnosis. The significance of the term as usually employed is defined by a quotation from this article: "The term typhomalarial fever, as Woodward later pathetically remarked, has been used extensively by many physicians to denote any obscure febrile affection which offered diagnostic difficulty." Woodward introduced the term into the United States; hence the pathos. The difficulty in diagnosis in these light cases can scarcely be better illustrated than by the following: The patient, a man, twenty-eight years



of age, called me to attend him January 4, 1898, complaining of an attack of diarrhea which had lasted three days. He said he had frequently had such attacks and thought this one was brought on by partaking liberally of a late supper. The stools were very numerous, clay-colored, and contained some mucus, but no blood. His temperature was 100.8° F., and his pulse 100. In spite of the numerous stools and the fever which next day reached 101.8° F., he had but little discomfort. The physical examination was negative except that the sclera were a little icteric. Under the administration of intestinal antiseptics the number of stools decreased and the patient felt brighter. On the 9th, as the temperature and pulse were normal the patient was allowed to go to his office. Three days later, he sent for me again, reporting that he had felt better on the 10th, but that the next day the diarrhea and fever had recurred. His tempera-

[1] Irving Phillips Lyon. Coincident Typhoid and Malarial Infection, Johns Hopkins Hospital Reports, Vol. VIII., p. 263.

ture was 103.2° F., pulse 96. The course of the fever is shown by the chart. He was put to bed on a milk diet. The physical examination was still negative. He complained of nothing except drowsiness during the day and of restlessness at night; the next day percussion showing the spleen to be a little large, a specimen of blood was sent to the Board of Health for a Widal test. A negative report was rendered. The stools were now of the peasoup character.

On the 17th the edge of the spleen was palpable. The urine failed to show Ehrlich's diazo-reaction.

My attention had shortly before been attracted by an article by Hiss, in the *Journal of Experimental Medicine*, on "A Method of Isolating and Identifying the Bacillus Typhosus," and to him I sent a specimen of the patient's stools. The next day, the 18th, and apparently the nineteenth day of the attack, his temperature was again normal. On the 21st the report on the feces was returned, stating that the typhoid bacilli had been found. Another specimen of blood was immediately sent to the Board of Health and a positive Widal reaction was obtained. The unusual feature of this case was the subsidence of fever on the eighth day of the disease. The well-known fact of the late development of the agglutination test in some cases needs no further comment. By a peculiar coincidence, during this patient's illness a report appeared in the *New York Medical Journal*, by Brill, on "A Disease Resembling Typhoid Fever."[1] He cited seventeen cases running a short course, offering nearly all of the classical symptoms of typhoid but not presenting the Widal reaction, and differing in minor details; he could afford no satisfactory explanation of the etiology of these cases.

Proof seems to be accumulating that there is a disease which resembles typhoid clinically and in such a case bacilli have been cultivated from the blood which morphologically resemble Eberth's bacillus, but differ in some respects. The essential point is that such cases give a negative serum reaction. These cases are rare. The case cited, of course, did not belong to this category, but in its course bears some resemblance.

A mild attack of typhoid, though usually running to a successful issue, is by no means to be looked upon with unconcern. Because the patient is comfortable and the temperature is low, a haste to comply with the patient's wishes may prove disastrous, resulting, perhaps, in a hemorrhage, as in the case cited. Two of the worst cases I have met with have been in relapses from exceedingly mild initial attacks. The rule that a patient should be carefully restricted until the temperature has been for some time normal holds for light cases as well as for severe ones. Living by the thermometer, however, is irksome for patient and physician and one is tempted to second the wish I have heard old practitioners express, that all thermometers might be at the bottom of the sea.

These little recrudescences may be due to various causes, *e.g.*, a too liberal diet, constipation or nervousness. A starvation temperature is also to be remembered. A patient of mine, a young man, whose temperature had been normal some time, discovered on one occasion that the thermometer registered a degree above normal, and was canny enough to attribute it to the excessive heat of the day and forced all the family to take their temperatures. Every one of them showed an elevation of one-half to one and one-half degrees above normal and the same result was obtained from other healthy individuals that day. I remember, when on service at the New York Lying-in Hospital, that one hot day all but one of a dozen patients in a ward registered a temperature from one-half to one degree above normal, which subsided with the cool of the evening.

One is prone to allow a patient convalescing from a light typhoid to resume his occupation too early, presuming on the rapid gain made in convalescence. I made this error in one of my cases and saw the patient later forced to withdraw from his business for a much longer time than would have been necessary, probably, had a longer period for convalescence been insisted upon.

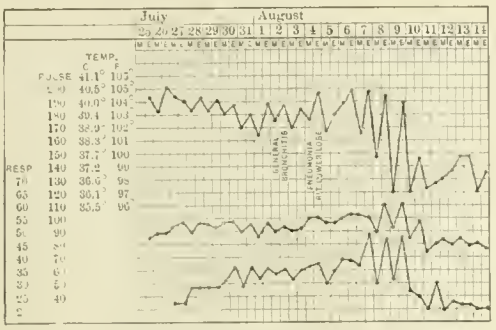
Amid the anxieties and perplexities of a serious case we are often neglectful of minor manifestations and are frequently surprised into harking back dimly to experiences of our own when the like is presented by others. We note the development of a functional murmur in a weakening heart, we determine the cardiac impulse and outline, study the condition of the arterial system, watch the various phases with the progress of the disease and then in our interest compare the notes on our previous cases, finding them, to our disgust, a Sahara; or, perchance, our attention is called to unusual rashes and we find upon our notes that in her relapse "M. W. developed a rash that itched and looked like urticaria" and look in vain for more regarding it; or remembering that another case showed a brilliant scarlatiniform eruption of extensive distribution, we find that no note at all has been made of it.

The respiratory tract in typhoid fever forms a chapter by itself. We expect some congestion of the upper air-passages in most cases of moderately severe typhoid, expressing itself by a slight cough or a mild degree of deafness. In many cases we have a bronchitis of varying intensity and far more rarely a pneumonia.

The case of the accompanying chart was one in which an exceptionally sharp bronchitis prevailed. Note the respiration curve during the first week or ten days. I feared a bronchopneumonia in this case, but was never able to localize any area of consolidation. This case was removed to New Bedford Hospital during a seri-

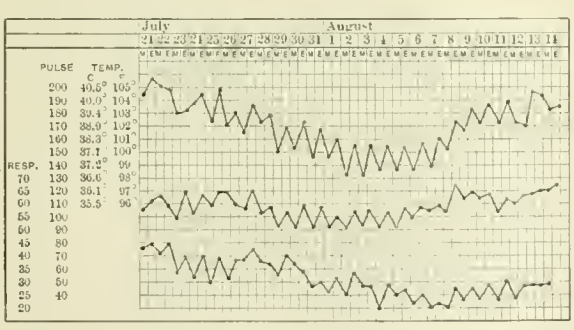
[1] N. E. Brill. A Study of Seventeen Cases of a Disease Clinically Resembling Typhoid Fever, but without a Widal Reaction, New York Medical Journal, Vol. 67, p. 77.

ous relapse which was followed by a second relapse with eventual recovery. The patient was forty years of age. In this case I got very gratifying results from the use of ice-bags in the



axillæ and groins as adjuvants to the sponge-baths to control the temperature.

Pneumonia may occur early in the disease and so dominate the picture that the typhoid is recognized only late or not at all; or it may occur later and, if at the height of the fever, produce so little change in the temperature curve as to be overlooked unless routine examinations of the chest be made. If it occur late, there is an exacerbation of the fever to give a hint of its presence. It is alwas a serious lesion. Pneumonia in typhoid fever may be lobar, lobular or of the so-called hypostatic variety and the organism present may be the micrococcus lanceolatus or Eberth's bacillus. As an example of a late pneumonia I quote the following:



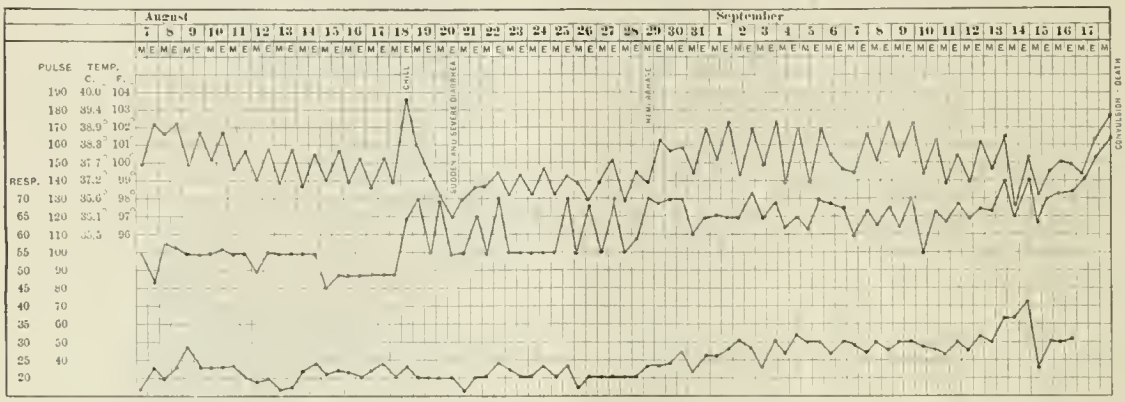
In July, 1898, there came under my care a lad of sixteen years with a well-developed typhoid. He was apparently in the second week of the attack and had a temperature of 104.2° F. and a pulse of 88. He was drowsy, had a little headache, was constipated and an examination revealed rose spots and an easily-palpable spleen. He had a rather severe type of fever, the nature of which you will see by consulting the chart. Five days later, on what was reckoned the fifteenth day of the disease, a note was made that the patient had a slight cough and a few râles were detected at the left base. On the eighteenth day sibilant and coarse râles of a general bronchitis were heard over both sides of the chest. The next day the signs were more marked and the breathing was a little asthmatic in character. On the morning of the twentieth day there was, in addition to the râles, restricted breathing over the lower right chest posteriorly, and in the evening over this area there were dulness, bronchial breathing, and subcrepitant râles. On the twenty-second day, in addition to these signs, the breathing became restricted over the left base. The respiratory rate was increasing during this time to 40 above. On the twenty-fourth day the temperature dropped from 104 to 99° F., went up the next day to 104° F. and dropped to 97° F. in the morning, only to repeat this change in the next twenty-four hours, after this crisis remaining normal with slight fluctuations. On the twenty-sixth day, the day of the final drop, the bronchial breathing could no longer be heard and from this time on resolution occurred, though all signs did not clear up for three or four weeks. The right lower lobe I considered to have been the site of a lobar pneumonia. The restricted breathing over the left was due, I think, to hypostatic congestion.

Crises do occur in typhoid fever, but according to Hare they are rare. This crisis I think due to a defervesence of the pneumonia, the febrile reaction due to the typhoid having abated during its continuance.

Now and then there comes to us a case of more than usual interest, replete with difficult problems and rare manifestations, finally leaving to us as a heritage the everlasting why? Such is the case that follows, which even at the risk of tiring you, I beg to be allowed to report somewhat in detail.

The patient was a woman sixty-one years of age, with a decided tendency to corpulency. She had always been remarkably free from ailment of any kind and was the picture of health at the time of the attack. At that age typhoid fever is not common, as you know, and the consensus of opinion among writers is that it is a grave disease, "the mortality increasing with the years after forty" (Hare); and yet the temperature curve in these cases is not high and is apt to be irregular. I first saw her on August 4, 1899. She said she had not been feeling well for two weeks, had a poor appetite, was constipated and had a headache each morning. Two days before and again on this day she had had a chilly feeling followed by some fever. Her temperature was 101.5° F. and her pulse 100. The physical examination was negative. Her bowels were moved freely and the next day as her condition showed no improvement she was sent to bed and put on a milk diet. Two days later her temperature reached 102.2° F., and then steadily decreased, as may be seen by the chart. Her illness promised to be a very comfortable one and the progress was favorable until the end of the second week (from the time she took to her bed), when, after a sudden chill, the temperature rose to 103.8° F. and the pulse to 120. The temperature subsided the next day and re-

mained almost normal for ten days, undergoing excursions of not more than one degree. I do not know what was the cause of this sudden rise. During this attack no spots were seen and it was impossible to make out splenic enlargement a change in the phase of the typhoid or a dysentery? I believe it was the latter. It came on simultaneously with a sudden outbreak of a number of cases in the town, was accompanied by a great deal of abdominal pain, traces of blood



on account of the thickness of the abdominal parietes.

Mild as this initial attack was as regards temperature and personal comfort, no doubt the chart has revealed to you one factor significant of low resistance, the pulse-rate, which had been persistently high.

Two days after this chill, August 20th, the weather suddenly became excessively warm and within twenty-four hours I was called to see ten or a dozen cases of diarrhea, some of them dysenteric in character, passing blood and mucus. These sudden epidemics, if I may so dignify them, coming on within a few hours, I have met again and again in my summer practice at the seashore; they appear usually with marked changes in the weather and are attributable in most cases to no indiscretion in food, drink or exposure. On this day, in common with other cases, the patient had a sudden and very severe diarrhea. The stools were flecked with blood and caused a great deal of abdominal pain. Tenderness was marked over the sigmoid flexure. A cathartic of castor oil was given and intestinal antiseptics and small doses of opium were employed with promising result. For five or six days the condition improved and then the stools became more numerous and very offensive. The tenderness over the sigmoid increased. On the 28th she had a fairly comfortable day, but at eleven o'clock the next morning had an intestinal hemorrhage of from a half pint to a pint. Ice was applied to the abdomen and morphine administered hypodermically.

From this time on you will note that the character of the chart changes. The temperature rose, the curve became very irregular and the pulse curve grew more ominous every day. The patient was suffering a relapse of the typhoid and a severe one. Hare says that relapses after mild initial attacks are more common than after severe ones. Was this attack of diarrhea simply in the movements and tenderness in the left iliac region which increased up to the time of the hemorrhage. The hemorrhage may have been due to a dysenteric ulcer or a typhoid ulcer, probably the latter, the process of ulceration being hastened by the colitis.

Those of you who have read the highly interesting and instructive Gloustonian lectures on The Typhoid Bacillus and Typhoid Fever by P. Horton-Smith[1] will recall his discussion of relapses in typhoid fever. Briefly he considers that auto-intoxication plays an important rôle and shows that the action of typhoid toxins is heightened in virulency in the presence of other toxins, even those of the normal inhabitants of the intestinal canal, *e. g.*, bacillus coli, and shows that in turn other organisms and especially the bacillus coli increase in number and virulency in the presence of the bacillus typhosus. Conditions which encourage the growth, then, of other germs in the intestinal canal, heighten the virulency of and reduce the resistance of the system to the typhoid toxin.

These truths seem to be exemplified in this case. Whatever the germs may be that are responsible for the simple dysentery we are accustomed to see, as in this case, whether the bacterium coli commune, the proteus vulgaris, the streptococcus or a staphylococcus, their presence and growth may explain this relapse and its very severe character.[2] During the first week of the relapse the stools became more infrequent and tympanites of a marked and persistent character intervened. The patient became more drowsy and grew weaker, the pulse running from 110 to 130. During the second week the condition was practically unchanged, except for a more marked apathy and the appearance of subsultus tendinum. In the middle of the third

[1] Lancet, Vol. I., 1900, p. 821.

[2] With reference to this, see recent article by Vedder and Duval on "The Etiology of Acute Dysentery in the United States," Journal of Experimental Medicine, Vol. 6, p. 181.

week the patient began to be delirious and the evacuations became involuntary. The febrile excursions were more marked and the pulse was weaker. At the end of the week the patient was fast failing, râles appeared in the chest, respiration became rapid and arhythmic and soon Cheyne-Stokes in character. On the last day of her illness the pulse went up to 166, the respiration to 44°, though râles in the chest were gone. In the morning it was noticed that the legs were stiff, and early in the afternoon the left hand began to twitch, followed by clonic spasm of the masseters and shortly after by a general convulsion. Two hours later another convulsion occurred, beginning with nystagmus, strabismus involvement of the facials, producing the risus sardonicus, never to be forgotten when once seen, and spreading to the whole body. This lasted twelve minutes in spite of the use of amyl nitrite, and of chloroform. Two hours later another convulsion ensued in which she died.

Convulsions in typhoid are not of common occurrence and yet nearly all the writers who have treated of the disease extensively mention them. In many of the cases meningitis is suspected and, indeed, true meningitis does exist, due to the streptococcus, to the pneumococcus or, in rare instances, to the bacillus typhosus; in other cases only a simple congestion of the meningeal vessels is present and several instances have been recorded in which the postmortem findings were absolutely negative. Thrombosis of the cerebral sinuses or arteries may cause local or general convulsions. As an autopsy was not secured in this case the cause of the convulsion can at best but be conjectural.

As regards treatment I have little to say. My own method is the one so largely adopted at present, consisting simply of keeping the patient on a milk diet and controlling temperature by baths and sponging. Theoretical considerations appeal strongly for intestinal antiseptics, but clinical evidence in their behalf arouses no enthusiasm, while what the Germans call the *Nebenwirkung* of the drugs always haunts one as possessed of unpleasant possibilities. Too rigid observance of milk diet, an observance which in some instances becomes slavish, is to be decried. I am sure I have seen unpleasant consequences in a case of my own by failing to appreciate the folly of continuing a food that the bowel clearly would not dispose of, simply because it was labeled milk.

To one procedure I desire to call your attention, if it is not already familiar to you, and that is the prophylactic use of urotropin. I remember the interest with which I read Mark Richardson's article in the *Journal of Experimental Medicine* (1899) "On the Value of Urotropin as a Urinary Antiseptic, with Especial Reference to Typhoid Fever," on account of the promise it held out. He had called attention the preceding year in the same journal to the fact that the urine of typhoid patients in 25 per cent. of the cases he had investigated showed the bacillus typhosus and that they could be found long after convalescence—week, months and even years. The statement requires no comment on the danger of dissemination it entails. He found that in every instance the use of urotropin caused disappearance of the germ in a short time. He advises its use for ten days at the end of the fever. His work has since been corroborated by other observers, notably by P. Horton-Smith. As no harm has been noticed in prolonged use of the drug, one can give five grains three times a day for three or four weeks, beginning as the temperature approaches normal.

400 West End Avenue.

ADRENAL SUBSTANCE IN THE INTESTINAL HEMORRHAGE OF TYPHOID FEVER.

BY WARREN COLEMAN, M. D.,
OF NEW YORK.

The local hemostatic action of adrenal substance on various mucous membranes is well known and needs no further comment. Adrenal substance exerts a similar hemostatic action when administered internally, locally on such portions of the mucous membrane of the alimentary tract as it may reach and also upon various bleeding areas while circulating in the blood. Reports of such action have appeared and are appearing in the literature from time to time; for example, adrenal substance has been used successfully in hematemesis from gastric ulcer and cirrhosis of the liver, in hemoptysis and hemorrhage from uterine fibroids; but, so far as I am aware, it has not been used in the intestinal hemorrhage of typhoid fever. During the past two years I have treated five such cases with adrenal substance. Four of the patients recovered, though in two of them the hemorrhage was very severe. The fifth patient died of toxemia and exhaustion several days later and not of hemorrhage, as was shown at the autopsy. While I am not prepared to say that recovery in the four cases was directly due to the action of adrenal substance, I feel that, in view of our utter helplessnesss when using the ordinarily recommended hemostatics in the intestinal hemorrhage of typhoid fever, I am justified in advocating the free administration of adrenal substance in these cases. Certainly no harm can be wrought by this treatment when ordinary care is taken, for even very large doses of adrenal substance may be administered without deleterious effects, as happened in one of my cases owing to an order which was misunderstood by the nurse.

A brief account of two of the cases will suffice to illustrate the action of adrenal substance in intestinal hemorrhage.

Case I.—Male, aged twenty-seven years. Very severe hemorrhage early in the evening of September 23d, the patient losing from three to four pints of blood. He was immediately given fifteen grains of adrenal and the dose was repeated every hour during the night. There were slight

hemorrhages—at least blood was passed in the stools—at one and two-hour intervals the same night. The patient's temperature was 103° F., and an ice-coil was kept on the abdomen. On the following day fifteen grains of adrenal were given three times a day, and the ice-coil was continued until September 26th; no further hemorrhages occurred after the first night.

Case II.—Female, aged forty-three years. Severe intestinal hemorrhage September 22d. Adrenal substance was immediately given, fifteen grains every two hours during the day and every four hours during the night. The next day the stools were tinged with blood, and adrenal was given in fifteen-grain doses three times a day. On the third day only faint streaks of blood were present in the stools, and treatment was continued in the same manner. No further hemorrhage occurred.

In view of the success which has attended the administration of adrenal substance in these five cases, my present plan, on assuming charge of a case of typhoid fever, is to order five-grain powders to be kept in the sick-room and to give instructions to the nurse to administer one powder on the first sign of blood in the stools, repeating the dose every hour until I can be reached.

When the patient is conscious the powder may be placed on the tongue, chewed a little and swallowed with a little water. In a profound typhoid state, the powder may be given in suspension in water or in a little milk. Occasionally, the first dose produces slight nausea; this did not occur in any of my cases, however. When nausea follows the administration by mouth, ten grains of the powder may be given by rectum, if the diarrhea is not too frequent, and the dose repeated every hour or two. If neither the stomach nor rectum will tolerate the drug, Schaffer's suggestion of an intravenous injection may be tried, but not more than two or three grains should be so given.

I have also had a case of purpura hæmorrhagica with severe hemorrhages from the nose, gums and bowels, and extensive cutaneous extravasations, in which adrenal substance was successfully given. The extent and the severity of the hemorrhages will be appreciated when I say that the patient was compelled to sit up in bed and hold a basin to catch the blood that was continually flowing from the nose and mouth. On entrance to the hospital, he was immediately put upon fifteen grains each of adrenal substance and calcium chloride, three times a day. This treatment was continued for the six following days with gradual subsidence of the hemorrhages and their complete cessation on the fifth day. Of course, in this case it is impossible to say how much of the benefit resulted from the adrenal and how much from the calcium chloride.

To illustrate the local action of adrenal substance in the stomach a recent letter of Soltau Fenwick[1] to the *British Medical Journal* may be quoted. He writes that in severe hematemesis he has abandoned all other remedies in favor of adrenal substance and he believes that he has saved the lives of at least five patients in the last eighteen months by this treatment. His plan is to give ten ounces of a freshly-prepared decoction of adrenal powder, containing two grains to the ounce, as soon as possible after the beginning of the hemorrhage, and to repeat the dose in two hours. In two cases in which melena was the only symptom he gave three doses in four hours. He has obtained the best results in comparatively recent ulcers near the cardiac end of the stomach. In chronic ulcers of the pylorus, when the eroded vessel was of large size and embedded in firm connective tissue, he found the adrenal to be of little use. He has also used with benefit enemata of adrenal substance in inoperable cases of cancer of the rectum for the control of hemorrhage.

[1] Brit. Med. Jour., 1901, Vol. II, p. 1596.

PATHOLOGY OF TYPHOID FEVER.[1]

BY R. ALEXANDER BATE, A.B., M.D.,
OF LOUISVILLE, KY.
ADJUNCT PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND LECTURER ON HYGIENE, HOSPITAL COLLEGE OF MEDICINE, LOUISVILLE, KY.

THE bacillus typhosus within the system is the cause of typhoid fever. Eberth, Klebes, Gaffky, Koch, Arthaud, Pfeiffer, Friedlander, and many others have identified this bacillus. It is about one-third the diameter of a red blood-corpuscle in length, one-third as thick, and it is rounded at the extremities. A shining rounded body may sometimes be observed at either end or in the center, which may be either a spore or a protoplasmic degeneration. The bacillus occurs singly or many bacilli may be joined together, end to end. It possesses vibratile cilia which permit its characteristic motility. Its general appearance differs somewhat according to the culture media employed.

The life of the bacillus is uncertain. Active bacilli have been found in the human fifteen months after convalescence. They seem to continue to live indefinitely in filth, in privy vaults, and in moist earth. They multiply in water and maintain their vitality in ice. Sunlight destroys them, however, in a few hours. Electrolysis also destroys them. Zeit (*Jour. of Amer. Med. Assoc.*, Nov. 30, 1901) reports the death of typhoid bacilli in bouillon cultures after exposure to a continuous current of one hundred milliamperes for seventy-five minutes at a temperature of 102° F. The most frequent media through which they are conveyed to man are water, milk, sewage contamination, dust and shellfish, especially oysters. Flies also purvey the infection.

It has often been observed that the source of infection in milk was usually through the water employed to wash the cans or to dilute the milk, and that, if the organisms were respired, some were carried into the alimentary canal by food or drink. Some claim that the bacilli

[1] Read before the Louisville Pathological Society, Dec. 16, 1901.

must enter the system through the intestinal glands or by inoculation, never by the respiratory tract; but this is unproved. Any age may be affected by typhoid fever, the fetus *in utero* or the nonagenarian. Many observers have identified bacilli in the heart and spleen of the fetus and in the placenta. Hammernyk reported the case of a patient ninety years of age. The adolescent male, however, is most frequently affected.

Exhaustion of any kind predisposes to an attack, but influenza has been observed frequently to precede the disease. Pregnancy renders no immunity and the fetus is usually so affected that abortion, miscarriage or premature labor occurs in the larger proportion of cases. In this country the disease is most frequent in the fall of the year, the poison having been concentrated by the drougths of the summer; the disease is correspondingly less frequent during the spring, owing to the dilution of the poison by early rains. No race is immune, but temporary immunity has been observed in various individuals, and a second attack rarely occurs in the same individual.

Although the bacillus is in an active state when discharged in the excreta, it is generally believed that a period of extra-corporeal development occurs before the organism again infects the human. The period existing between the time of introduction into the system of the poison and the manifestation of symptoms is usually from ten to twenty days, in rare instances symptoms occur as early as two days. The bacilli have been found in the blood, in the lymphatics and in the tissues generally; especially in the blood from the rose spots, the intestinal glands, the spleen and the liver. They have been found in the gall-bladder, in the placenta, in the fetus and in abscesses. One case of an ovarian cyst, removed three years after an attack, is reported, in which active bacilli were present. They are excreted in the feces, in the urine and in the sputum.

The bacilli are the direct cause of the disease, but they liberate toxin in the system—the typhotoxicon of Brieger, the toxalbumin of Fraenkel and the ptomain of Vaughan—which is responsible for the fever, the vomiting and the purging that occur.

This toxemia produces changes in the blood. The fibrin is diminished, the leucocytes are increased and typhoid antibodies or enzymes are present in the blood. Loomis states the severity of an attack to be in direct proportion to the diminution of the fibrin of the blood and to the leucocytosis after the characteristic symptoms of the disease are manifest.

The enzymes in the blood digest the outer coat of the bacillus and thus cause the clumping and agglutination of the bacilli described by Widal. This altered state of the blood, according to Loomis, causes changes of the nature of parenchymatous degeneration in all the structures of the body. The spleen is the earliest to manifest these changes and is affected in ninety-eight per cent. of the cases; it becomes enlarged, soft and pigmented. The liver likewise becomes soft and flabby. Gould says that typhoid infection of the gall-bladder is probably always present during the course of the disease. Keen collected thirty-four cases in which empyema, cholecystitis, or ulceration were present without gall-stones; therefore these conditions were entirely dependent upon typhoid infection. Von Dungern reports a case of abscess about the gall-bladder which contained active typhoid bacilli fourteen and a half years after the disease. The kidneys undergo degeneration and may be the seat of infarctions. The urine becomes twice as toxic as the normal urine and contains certain aromatic bodies which give rise to the diazo-reaction of Ehrlich. Perinephritic abscesses are not uncommon. The heart, next to the spleen, is the seat of the most marked parenchymatous changes; it becomes soft and flabby and may be pigmented, or a condition similar to amyloid degeneration may occur. Thrombi are sometimes found within its chambers. The lungs are characterized by changes peculiar to typhoid fever, undergoing a "splenization" which is neither a true pneumonia nor yet static in type. Bronchial inflammation is so common as to have caused the name of bronchial typhus to be suggested. The larynx and Eustachian tubes may become ulcerated. The brain and nervous system are always affected. Cases of typhoid fever have been reported without the rose spots, cases without the intestinal lesions; but no case without the nervous phenomena has ever been observed. The walls of the stomach undergo degeneration and its glandular structures are so affected as to cease to secrete the gastric juices. Buchan (*Phil. Med. Jour.*, July 6, 1901) and Barjon and Lesieur (*Jour. Amer. Med. Asssoc.*, July 20, 1901) have reported cases of arthrotyphoid, or cases in which marked arthritis occurred. The muscles in general undergo two kinds of degeneration—a granular or fatty degeneration and a waxy or vitreous degeneration. The salivary glands undergo hyperplasia and pigmentation. The skin is the seat of a characteristic lenticular eruption, beginning between the sixth and and twelfth days. These so-called rose-colored spots vary in size from a point to a line and a half; they may coalesce and are most abundant over the abdomen.

These changes are regarded by some to be as constant a phenomenon in typhoid fever as is the rash in scarlet fever.

The subcutaneous cellular tissue may become the seat of ulceration or furunculosis. The mesenteric glands undergo changes similar to those of the intestinal glands. It was formerly said that, if there were a pathognomonic lesion in medicine, it would be the intestional lesion of typhoid fever. Typhoid fever, however, has been observed by the medical world at large for about fifty years only, and even in the last year additions have been made to its pathology.

In this paper it is especially desired to empha-

size the probable pathologic conditions in those cases of typhoid fever which are apparently shortened in duration. According to Loomis there are three varieties of changes that occur in the intestinal glands. The first and most common type is that in which the mucous membrane of the ileum, the Peyerian patches and the follicles near the ileocecal valve undergo a catarrhal inflammation during the first week of the disease. During the second week the inflammation of the mucous membrane subsides, increasing the hyperplasia of the glands, which progresses to ulceration, to be followed by sloughing or necrosis in the third week and cicatrization or repair in the fourth week. Intestinal perforation and hemorrhage may occur with these changes.

In the second or next most common process the termination is by the tissue between the follicles remaining infiltrated and elevated while their contents are absorbed, or individual follicles of the agminated glands rupture and discharge their contents into the intestine, leaving depressions which give the glands a reticulated appearance.

The third variety of pathological change in the intestinal glands is perhaps the least frequently exposed to the eye of the observer. However, if all the glands affected in all cases of typhoid fever could be counted and their entire course observed, it is my personal belief that this process would be found to be by far the most common of the three varieties of changes. Loomis best describes these changes: "During the first week there occurs a catarrhal inflammation of the intestinal mucous membrane, most marked about the Peyerian patches, with a medullary infiltration of these and the salivary glands. The mucous membrane becomes hyperemic, the glands become enlarged and elevated, the co-called shaven-beard appearance. These changes begin within forty-eight hours after the onset of the disease, but are not fully developed until the end of the first week. During the second week the hyperemia disappears from the mucous membrane, and, instead of hyperplasia occurring in the follicles, instead of the slough or ulcer forming, instead of the follicles remaining infiltrated and elevated and the glands rupturing, the new elements in these ductless glands become disintegrated and undergo absorption and in this way gradually undergo resolution." Thus by the end of the second week, without ulceration, the process is complete.

This is the classical pathological procedure in the mesenteric glands. This is the change that occurs most frequently in the typhoid of children, in whom the duration of the disease is never classical, but practically always shorter than in the adult. Most probably this is the process that occurred in the cases alluded to by Gould (*Phil. Med. Jour.*, March 3, 1900), who says that, while the intestinal tract exhibits the lesion of the morbid process in the vast preponderance of cases, it has now been definitely established that the intestines may be uninvolved. The disease may appear in the form of a true general infection or septicemia; or be localized in one or another or several viscera, as the spleen, the lungs or pleura, the cerebral meninges, the kidneys, etc. This absorption, without ulceration, is probably the classical process in relapses in which the fever frequently ends almost by crisis on the fourteenth day of the relapse. This is believed to be the change that occurs in by far the greater proportion of glands involved when the fever ends in the third week instead of in the fourth week, which latter has been regarded as classical. This is believed to be the change that occurs in a large number of cases observed by almost every practitioner, and in similar cases recorded by Loomis, Pepper, Osler and many others, in which the disease has lasted only two weeks; many of these cases had no medical treatment, and are referred to in textbooks as abortive and ambulatory typhoid. Resolution by absorption and not ulceration is unquestionably the process that took place in the cases reported by E. Fraenkel, A. Lambert, Henshaw, Brennan, Rumpf, Von Jaksch, Kraur, Walger and others, in which the disease was limited to less than fourteen days' duration by means of serum treatment. These reporters alone observed this limitation in more than a hundred cases.

Many cases are now on record in which autopsies have shown no intestinal ulceration, yet bacilli were obtained from the spleen and other structures. Ophuls (American Year-Book of Medicine and Surgery, 1901) describes a case of typhoid infection without intestinal lesions which occurred in a man of twenty-four who was admitted to the hospital in a semi-conscious condition. The diazo and Widal reactions were positive. The patient died a week later. The necropsy showed enlargement and softening of the spleen and lymph-glands, necrosis in the liver and multiple hemorrhages in the mucous membranes of the genito-urinary tract; bacteriological examination showed in the spleen large numbers of bacilli which had the characteristics of typhoid bacilli. Ophuls believes that in a certain number of these cases, which are apparently without intestinal lesions, infection has taken place in the usual way, through the intestinal mucous membrane, but that there has been no ulceration of Peyerian patches and the swelling has disappeared. McPhedram (*loc. cit.*) describes another case in which typhoid bacilli were found, but there was no intestinal ulceration; this patient died forty days after admission into the hospital.

An editorial in the *Journal of the American Medical Association*, July 30, 1901, entitled "Abenteric Typhoid Fever" says in substance that it has been properly pointed out that the lesions of typhoid fever are by no means confined to the intestinal tract, which may, and in fact occasionally does, escape involvement entirely. The article further cites the case of arthro-

typhoid of Barjon and Lesieur (previously referred to) in which the post-mortem showed no ulceration of the bowel.

Wm. A. Dickey (*Therapeutic Monthly*, 1901), considering the question of intestinal ulceration in all cases of typhoid, says, "This position can no longer be maintained," and refers to the paper of Vallaird, of Paris, read in 1890, in which a case was presented in which no intestinal ulceration occurred. Banti and Adnot each have reported cases. Osler has reported a case of typhoid in a boy, in which there was no disturbance of Peyer's patches. Flexner and Harris (of Johns Hopkins) reported a case in a man sixty-eight years old in which there was no intestinal ulceration. Dickey further says, "Numerous other cases are reported, so that we can no longer look upon the disease as one affecting the alimentary canal only, but rather one of a general character, a modified septicemia." So many cases are now on record that the impartial investigator can no longer doubt the frequent occurrence of genuine typhoid fever without intestinal ulceration. The action of the typhoid antibodies and other pathological conditions are not only still obscure, but can be studied only by the few.

At present it has been observed (American Year-Book of Medicine and Surgery, 1901) that (1) a single intraperitoneal injection of a typhoid culture into a guinea-pig results in the formation of antibodies; (2) the antityphoid power appears in the serum at about the fourth or fifth day; it increases until it reaches the maximum about the eleventh or twelfth day, when it diminishes but is still present a month after the injection; (3) the antityphoid power is small in the liver, the kidneys, the suprarenal bodies and the omentum. The value of the antityphoid power of the peritoneal exudate sometimes approaches that of the serum, but never surpasses it; (4) the bone-marrow and spleen are frequently more active than the serum; (5) the lymphatics and the blood may each be concerned in the formation of these antibodies; (6) the antityphoid action of these bodies has been positively demonstrated; (7) there may be an agglutinating principle separate and distinct from these antibodies.

It is only in recent times that any attempt has been made to separate these constituents of the blood. But certainly the antityphoid strength of a serum, very frequently corresponds with the power of its agglutinating action. The tendency of modern pathologists is to the opinion that true typhoid toxemia is limited in many instances to fourteen days, and that the manifestations after that time are usually dependent upon intestinal ulceration.

Therefore, since pathology has shown that no intestinal ulceration is essential to typhoid fever, and since true typhoid toxemia is often limited to fourteen days, and as the action of the typhoid antibodies and enzymes becomes better understood, it seems not unreasonable that therapy may soon claim to so modify the course of typhoid fever as to limit its duration in the great majority of cases to fourteen instead of the too classical twenty-eight days.

Second and Burnett Streets.

MEDICAL PROGRESS.

SURGERY.

Surgery of the Posterior Fossa.—While results from work on the posterior fossa and its contents have not been productive of most brilliant results, still life has been prolonged and made bearable and in a number of cases saved. The opportunity has been afforded to report several such cases to C. F. Barber (Brooklyn Med. Jour., Mch., 1902). In operating, he prefers opening the skull in the posterior fossa, as the various parts are more readily exposed, and drainage is more efficiently accomplished. In the first case pressure symptoms were marked and a cerebellar neoplasm was thought of. On opening the cranial cavity through the posterior fossa, a goodly quantity of fluid escaped and the pia seemed to be the site of a tuberculous inflammation. The wound was partially closed and silkwormgut drainage inserted. The fluid escaped for several days and symptoms disappeared entirely; recovery was perfect. In another case marked by attacks of tonic and clonic contractions of the extremities, loss of sense of direction, strabismus, headaches, areas of anesthesia, a diagnosis of cerebellar tumor, solid or cystic, was made. The operation was instituted in the same way and on lifting up the cerebellum a cyst was ruptured. The wound was closed, with drainage and in three days consciousness returned. Other symptoms were ameliorated, but in three weeks the patient died. The autopsy showed a cyst in the other hemisphere which had not been discovered. The author draws attention to the advantage of drainage in the most inferior point of the cranium as against puncture through the fontanelles and direct drainage of the lateral ventricles.

Gastrojejunostomy.—An interesting case in which this operation was done and which came to autopsy six years later is reported by A. H. Cordier (Jour. Amer. Med. Assoc., Mch. 1, 1902). The reason for the operation was the presence of a pyloric stenosis due probably to contraction from the healing of a non-malignant ulcer. The stomach was found very much dilated, with the pylorus low down, and the anastomosis was made with a Murphy button at a point in the anterior wall about four inches from the pylorus. A portion of jejunum about eighteen inches below the pylorus was selected as the site of application. The patient made an excellent recovery and had no further symptoms referable to his previous condition. Six and a half years later he died as the result of an acute pneumonia. On autopsy a complete obstruction of the pylorus was found; the stomach had regained its former size, with the musculosa healthy and well developed, while the unused duodenum and jejunum were atrophied. The Murphy button instead of being passed *per rectum* had dropped back into the stomach and remained there until the time of death without causing any symptoms. As this accident has been urged as an objection against the use of the button, mention of such a case causes it to lose some of its force, and the author believes that the great advantages to be gained certainly outweigh this doubtful source of danger.

Gastric Ulcer and Appendicitis.—Appendicitis is a difficult disease to diagnose when the symptoms are

at all obscure. Among the lesions which may resemble it is perforated ulcer of the stomach. C. A. B. HORSFORD (Lancet, Feb. 15, 1902) reports the case of a patient, thirty-two years of age, married. Five days previously, before breakfast, she had an attack of pain in the abdomen most marked in the right hypochondrium. Vomiting persisted at intervals throughout the day; there were jaundice, tenderness over the gall-bladder, flaccidity of the abdomen without distention, normal temperature, and no signs of collapse. For two years she had suffered from indigestion with occasional vomiting, but never hematemesis. About a week after she was admitted to the hospital, the temperature rose to 100° F., and two days later another severe attack of pain occurred; the right leg was drawn up, and tenderness at McBurney's point and slight bulging in the right iliac fossa were marked. Bile-stained vomiting followed by stercoraceous vomiting appeared in the evening. The temperature was then 100° F. and the pulse 95. Nothing definite was made out through the vagina. A diagnosis of appendicitis was made, but operation was not considered necessary. She soon became decidedly worse. The pulse and temperature remained about the same but the abdomen had become generally distended, especially in the hypogastrium and in the right iliac region. Liver dulness was present and there was dulness over the lower part of the abdomen. By the vagina a tumor mass was now made out, which was confirmed by the rectum, and a large amount of fluid was felt in the pelvis. The patient suddenly grew worse and died before operation was undertaken. At the autopsy it was found that an ulcer of the stomach had perforated and that an abscess had formed between the coils of the small intestine in the right iliac fossa, extending downward into the pelvis and upward along the ascending colon. This case is rare in its great similarity to appendicitis and therefore deserves notice.

Operative Interference in Spinal Fracture.—Spinal operation has proved comparatively free from the drawbacks attending intracranial surgery. This fact, together with the serious, painful and usually fatal nature of the lesion under consideration, renders the question pertinent whether it is not wise to operate early in the hope of relieving the pain and improving the course of the average case. The conclusions of G. L. WALTON (Boston Med. & Surg. Jour., Mch. 6, 1902) are as follows: (1) There are no symptoms which establish (otherwise than through their persistence) irremediable crush of the cord. (2) While total relaxed paralysis, anesthesia of abrupt demarcation, total loss of reflexes, retention, priapism and tympanites, if persistent, point to complete and incurable transverse lesion, the onset of such symptoms does not preclude a certain degree of restoration of function. (3) The prognosis without operation is grave. (4) While the results of operation are not brilliant, they are sufficiently encouraging to warrant one in making the practice more general. (5) In most cases it will be wise to operate within a few days of the injury; but a delay of some hours is advisable, partly on account of shock and partly to eliminate the diagnosis of simple distortion. (6) There is no infallible guide as to the extent of the lesion. The operation, at the worst, does not materially endanger life nor affect unfavorably the course of the case, and may, at least, reveal the lesion and lessen the pain; it may sometimes save a patient from death or invalidism of the most distressing character. Instead of selecting the occasional case for operation, one should rather select the occasional case in which it is contraindicated (the patient with great displacement of the vertebræ, the patient with high and rising temperature, the patient plainly moribund, the patient still under profound shock). (7) The dura should be opened freely; it need not be sutured; drainage is not necessary.

Adrenalin in Local Anesthesia.—The addition of some active local hemostatic to the solutions in general use for the production of local anesthesia in operations is a plan which must strike every surgeon as at least suggestive. The experiment has recently been made and with considerable success, by C. A. ELSBERG (Amer. Med., March 1, 1902). Experimenting with adrenalin chloride, as supplied in the market, he finds that its addition in the proportion of from 1 to 5,000 to 1 to 20,000 solutions has a distinct value in minor operative work in that it almost completely abolishes oozing from the wound. Contrary to his expectations, there was no secondary bleeding or oozing, as has so often been described after the use of this drug. The pain after the operation was less than when cocaine or eucaine alone had been used. There have been no ill-effects; unfortunately, however, the experiment has not yet been made in larger operations, such as herniotomies, so that judgment as to its general applicability must still be held in suspense.

Pulsate et Aperitur Vobis.—In the history of a healthy-looking yeoman, about fifty years of age, as reported by JOHN DAVIES (Lancet, Feb. 22, 1902), one finds a record of tapping which it will be hard to equal. From 1896 to 1900 he was tapped one hundred and fifty times. The total quantity of fluid removed was over two hundred and fifty gallons. In October, 1900, he died of cardiac failure.

Burns from Celluloid.—Evidently some active legislation should be directed toward regulating the combustion point of toilet articles made from this very inflammable material, A. OGSTON (Lancet, Feb. 22, 1902), having had several serious cases of burns in patients who, wearing combs, etc., of imitation shell, had suffered fearful injury from their apparently spontaneous combustion, and wishing to establish some sort of intelligent standpoint from which to attack the nefarious manufacturers, conducted a series of experiments to determine if possible the etiology of these accidents. Control experiments were conducted by Professor Japp at the Chemical Laboratory of the University of Aberdeen. The conclusions of these experiments were as follows: (1) Celluloid artices of uncertain composition and dangerously explosive are everywhere sold and are in constant use; the conditions under which they may ignite in varying circumstances cannot be fully determined from experiments made in a physical laboratory. (2) Badly manufactured celluloid ignites at variable temperatures, which are so low as to make it unsafe for personal wear. (3) Restrictions should be imposed upon all articles which do not sustain without ignition a temperature equal to that sustained by well manufactured celluloid. (4) All celluloid articles for personal wear should have the words "ignitable" stamped upon them. (5) It is said that celluloid can be made incombustible by the addition of some chemical. If this be true, such addition should be made compulsory by legislative action.

Cleft Palate.—Because of the very vague proof afforded dogmatic statements by Treeves and others on the surgery of this malformation, the general trend of which teaches that no child, except under the most exceptional circumstances, should be operated on before the age of three years, W. ARBUTHNOT LANE (Lancet, Feb. 22, 1902) in a long and graphically illustrated article discusses the "pros and cons" of such limitations. Among others, he asks and answers very definitely the following pertinent questions: What is the best age for operation? What is the best method of operating? How and when can any complication, such

as harelip, be met to the greatest advantage? While there is perhaps nothing startlingly original about the details of his method of operation, save that it is clear and introduces several modified instruments which are necessary, because of the tender age of the patients, the age limit is, indeed, an innovation. He says that after operating on a very large number of cases the best results come from intervention during the fourth or fifth week. The only and sole contraindication possible is the depression arising from bad or insufficient feeding. The advantages of early operation are as follows: (1) The child bears the operation well; (2) but very slight subsequent discomfort is felt and the child will take food with satisfaction within an hour or two of the operation; (3) the amount of hemorrhage is very slight and it is easily controlled. The most important variation which one needs from the ordinary is a mouth gag with serrate edges, since these infants have no teeth to hold the gag in place, and, again, the average instrument has an unnecessarily powerful spring. In the presence of a complicating harelip, contrary to universal custom he leaves the lip untouched until the palate is repaired. All sutures should be passed from within out through the lip (the old harelip pins being discarded); these efficiently check hemorrhage and never can cause a scar.

Internal Derangement of the Knee-joint.—It may seem like a reversion to go back to Hey's old name, but J. M. Cotterill (Lancet, Feb. 22, 1902) gives very considerable proof that the more modern term is very often a very misleading and erroneous name for a condition which can rarely be diagnosed with exactness save by exploration. Most writers are agreed as to the etiology. Probably in most cases it is an internal twist of the femur on the tibia. Stepping from rapidly-moving cars is a frequent cause. Football is, of course, the great factor in causing this condition. Miners and others who habitually kneel at their work are frequent sufferers from "derangement" of the knee. Rarely, if ever, is the lesion brought about by direct trauma to the cartilage. The pathology is more or less in dispute. Many good writers assert that the external cartilage is invariably the one to suffer. Equally good authorities—Cotterill among them—declare that in 90 per cent. of the cases it is the internal which goes wrong. In a series of most instructive photographs he shows that a very large proportion of the internal cartilages are split transversely, the coronary ligaments remaining intact. This is what leads him to feel that the term "dislocation" is incorrect. To the symptoms and diagnosis he adds some differential points. If seen before effusion takes place the knee can always be flexed fully and painlessly; full extension always gives pain. This is a diagnostic point between cartilaginous damage and injury to the general joint tissues. It is also of value in distinguishing between an injured cartilage and a "loose body," this being characterized by pain now on flexion; now on extension. Furthermore, in this condition one gets the characteristic "locking" which is not seen in injured cartilage. As to the treatment there is a general consensus of opinion that flexion, rotation away from the injury and extension will habitually remove the offending tissue and that after its removal it frequently happens that immobilization for three or more weeks will enable the freshly-torn surfaces to unite. In the rare cases of marginal protrusion of the meniscus a pad is of possible value; in the commoner central displacements it is not so. The indications for operation are simple. A patient under mid-life, who wishes to be active, who has neither rheumatism nor tuberculosis and whose cartilage is frequently giving him trouble, should certainly be operated on. In incising the joint, Cotterill enters by the usual skin-flap, but cuts the capsule over the femoral rather than over the tibial surface, saying that otherwise it is not easy to determine how much the coronary ligamentous injury may have been traumatic and how much due to the operator's knife. Having exposed the cartilage it is dealt with as follows: (1) If wholly or to a greater part separated, excise it. (2) If separated from its anterior insertion into the tibia and curled into the joint, cut off the anterior portion as far back as the internal lateral ligament. (3) If much torn or frayed in front, do likewise. (4) If there be a torn tag or strip of the free edge of the meniscus projecting into the joint while the main part is in place, cut off the tag or strip and leave the uninjured part. (5) Under no circumstances is it advisable to stitch into place the cartilage or part of it, save occasionally when the injury is very recent. Removal of the cartilage is such a satisfactory proceeding that in suitable cases there seems no argument against excision. Nothing should be allowed to enter the joint; asepsis must be beyond all question. In two weeks the splint may be removed and the patient encouraged to move the joint a little in bed. Crutches may be allowed after three weeks. Violent exercise must not be thought of till after the fifth month.

Surgical Treatment of Quadriceps Paralysis.—A moderate number of cases of muscular paralysis, incurable by other means, have been benefited or cured by the surgical substitution of neighboring healthy muscles for those diseased. Another contribution to this subject is made by F. Krause (Deut. med Woch., Feb. 13, 1902) in which he describes a quadriceps paralysis in a boy of fifteen following anterior poliomyelitis. In addition to entire atrophy of the quadriceps, there was partial atrophy of the sartorius, much diminished contractility of the adductors, the semimembranosus and semitendinosus. The biceps was in good functional condition. In the leg, the flexors and peronei were least disturbed, but the calf muscles, tibialis anticus and extensor hallucis were almost entirely functionless. This condition was accompanied by a pronounced atrophy of the femur, tibia, and patella. Owing to the action of the flexors and the paralysis of the extensors, the leg was flexed on the thigh at an angle of 110° and with great effort could be brought to 145°. The weight of the body could not be sustained. The operative problem resolved itself into securing a stiff joint by an arthrodectomy or substituting the functionating flexors for the quadiceps. The latter effect could be gained by using the flexors on the posterior aspect of the thighs (biceps, semimembranosus and semitendinosus) when transposed, as extensors, and leaving the gastrocnemius and popliteus as flexors of the knee. Even if the latter failed to functionate, the weight of the leg itself would passively carry out the motions. The operation was briefly as follows: After appropriate incision the biceps was isolated and severed at its insertion into the tibia. Exposure of the quadriceps showed it to be entirely atrophied. An opening was then made in the vastus externus close to the periosteum at a level corresponding to the point where the biceps is free from the bone, and the biceps itself is pushed through. The gracilis, semimembranosus and semitendinosus were likewise isolated, then cut off at their insertions, and pushed through an opening in the vastus internus. The sartorius was also finally separated. As the common extensor tendon was too much atrophied to permit suturing, the muscles noted were attached directly to the patella. It was hoped that the weakened ligamentum patellæ would develop through use. Catgut was used throughout and the wound closed without drainage. An extension apparatus was applied to overcome the contraction due to

capsular ligaments and recovery was uneventful. In about seven months walking without assistance was readily accomplished. Movement of extension could be fully carried out and a slight degree of active flexion was possible. Three years after the operation the latter was possible to the extent of about 30° by the action of the gastrocnemius. All the muscles and the patella showed remarkable increase in development. In conclusion the author calls attention to the fact that no consciousness of the change of the musculature and its action was evident to the patient.

Death from Chloroform.—It has usually been considered that this anesthetic caused death by a paralysis of the ganglia in the walls of the heart, owing to the fact that without a sufficient dilution with air it passed rapidly from the lungs to the heart. This explanation will not account, however, for those cases in which chloroform is administered by drops or for those in which paralysis of the heart does not take place until long after the beginning of narcosis. Whether other factors may not be accessory to this is considered in an article by L. LAQUEUR (Deut. med Woch., Feb. 13, 1902) which was inspired by a fatal accident of this nature in his own practice. Autopsy in this case, that of a boy of fourteen, showed a persistent hyperplastic thymus gland, hypertrophy of the lingual tonsil, and marked enlargement of the spleen. As these phenomena have been observed in numerous instances by other observers, the author believes that their presence in children may be taken as a safe contraindication to chloroform administration. As persistence or hypertrophy of the thymus is often difficult to determine by percussion—for enlarged mediastinal glands may give rise to the same note—the presence of the hypertrophied lingual tonsil may be taken as a certain indication of the presence of the former. In addition any hypertrophy of the other lymphatic structures of the oropharynx should be noted. Such examination should always be made before chloroform anesthesia.

Deformities Resulting from Fractures.—The treatment of fractures, and of deformities arising from fractures, has recently been conceived in a more liberal spirit than heretofore. This has resulted from three chief causes, namely, (1) the freedom and enterprise conferred on surgery by antiseptic methods; (2) the proved value of early muscular movements and massage; (3) the Roentgen rays. In discussing the chief factors that singly or in combination form the substratum for pathological conditions, J. J. CLARKE (Med. Press & Circular, Feb. 26, 1902) gathers them under the following heads: (1) Psychical impression. Just as in minor wounds one naturally protects and guards the extremities without just reason or cause, after major injuries patients are apt to continue to nurse their disability, even though the lesion may have vanished. (2) Fibrous adhesions. These are the result of the organization of blood-clots either among muscle or within a joint in the neighborhood of a fracture; they constitute the primary indications for early massage and early passive movements. Massage helps by the relief of pain and spasm. Bivalve splints are of the utmost importance to enable the introduction of such treatment. (3) Muscular contractures. These are due to prolonged maintenance of incorrect postures. Their cure is often effected by massage and passive movements, but in some cases tenotomy may be required. (4) Angular deformity from faulty union. There is less excuse for this condition than formerly existed, because a radiograph taken through the splints will always clear up any doubts in the surgeon's mind as to juxtaposition of fragments. Although many devices have been produced for mechanically holding the bones in place, there is probably nothing better than stout silver wire, annealed by being passed through a flame and allowed to cool slowly. Osteoclasis or osteotomy may be called for and these are almost invariably singularly free from subsequent pain. (5) Shortening from overlapping of fragments. Illustrative cases of any success in treatment of this class of deformity will be of unusual interest. Here extensive myotomies, fasciotomies and tenotomies may be necessary. (6) Pseudo-arthrosis. There is nothing new regarding the treatment of this type. (7) Exuberant callus. This is most commonly found in fracture of the radius above the attachment of the pronator radii teres. Gighli's wire saw is in many cases the best instrument. (8) Separated epiphysis. As this occurs frequently in young children the Roentgen rays are of little help, no image of the cartilaginous epiphyses being given in the radiograph. It is better, if possible, to avoid wiring in these cases, owing to the fact that the foreign body in the bone often interferes with future growth; furthermore, the softness of the bone renders such ligation very difficult. (9) Fractures in the neighborhood of joints. These are frequently complicated by dislocation and in case the ordinary means fail, we should certainly follow the advice of McBurney in wiring the fragments. (10) Fractures involving joints. The two most common are fracture of the patella and of the acromion; although the technic of these operations is not difficult, they should not be undertaken without a certain regard to the constitution or condition of the individual case. In gouty individuals there is some form of rarefying ostetitis which often interferes seriously with success; furthermore, these cases do not take an anesthetic kindly. In operating upon the elbow it is convenient to open the joint from behind by chiseling through the base of the olecranon. This gives a particularly good view of the radial head and is the operation to be recommended for its removal; the olecranon is subsequently wired back in place. (11) Ischemic contracture. This troublesome deformity may exist alone or may complicate other deformities. It is commonest after fractures of the humerus. In the absence of other elements it can be alleviated by tendon elongation of all the flexor tendons above the wrist. This, however, is a difficult procedure and should never be undertaken until every other form of treatment has been exhausted. If an attempt be made to remedy the deformity by removing parts of the radius and ulna an ununited fracture is the result.

NEUROLOGY AND PSYCHIATRY.

Adiposis Dolorosa.—Only twenty-six cases of this rare disease have thus far been reported, of which all but three were described as found in women. Two additional cases are reported by F. X. DERCUM (Phil. Med. Jour., March 1, 1902) which present some interesting complications. Both were of the localized diffused form of the disease, the preponderance of fat in the male patient being found on the trunk, in the female on the thighs. While fatty deposits and pain are the two most prominent symptoms usually described, the author lays equal stress on the marked asthenia and psychic or general nervous symptoms. The asthenia does not appear to depend directly on the fatty deposit, for in the woman a few simple movements of the arms brought on excessive fatigue, although very little fat was developed there. A similar condition was present in the man. In addition to the usual neurasthenic disturbance, epilepsy of the grand mal type and preceded by a gastric aura was present in the male patient. Interesting eye phenomena were noted in both cases. In the man, accumulations of fat could be felt in the orbital cavity, and if the eyes were tested separately, moderate dilatation of the pupil in accommo-

dation was noted instead of contraction. In one eye of the woman was noted a circinate retinitis—a mass of partly fibrinous and hemorrhagic exudate in the center of the retina surrounded by crescents of fatty degeneration in Müller's fibers. As the patient was considerably younger than the age at which the latter conditions are usually found, the retinal changes were probably dependent on the same pathological cause.

Progressive Saturnine Paralysis.—Discussing the nervous manifestations of chronic lead poisoning, G. Bazzicalupa (Gazz. delgi Osped., Feb. 9, 1902) calls attention to the cerebrospinal syndrome represented by progressive paralysis. Analysis of an individual case, in which all etiological factors other than inherited neuropathic tendency and chronic lead-poisoning could be excluded, is used as the basis of an argument tending to establish the identity of saturnine progressive paralysis with dementia paralytica due to other morbific causes. The clinical picture duplicates that of the latter disease in its various stages; anamnestic data and certain concomitant symptoms characteristic of saturnism giving the key to causation of the malady. In view of the facility with which chronic lead-poisoning can be induced through canned food, occupation, etc., the author holds that saturnism should be considered as a possible etiological factor in all cases of progressive paralysis.

Intermittent Limping Due to Obliterating Arteritis.—A peculiar case is reported by C. L. Dana (Med. Rec., Feb. 22, 1902) in which the patient, while walking was suddenly siezed with pain, stiffness and weakness in the left foot. Disagreeable sensory disturbances were also present and the pulsations in the popliteal and plantar arteries could not be felt. Subsequent attacks followed and similar signs were later present in the left arm. Several instances of such cases have been reported and are due to arterial sclerosis, causing obliteration of the smaller trunks, also to disease such as aneurism of the larger arteries. The condition is chronic in course and may lead to gangrene or symptoms resembling erythromelalgia or Raynaud's disease. It affects usually one leg, but may attack both and may affect the arm. It occurs in middle-aged people of neurotic temperament and is associated with exposure, alcoholism, gout, diabetes, excessive use of tobacco, and with syphilis.

Cerebral Syphilis Simulating General Paresis.—In this case, reported by E. Brissaud and A. Péchin (Le Progrès Méd., Jan. 18, 1902), the symptoms were rather marked, and there were too many isolated phenomena to indicate positively a diffuse periencephalitis. There were epileptiform convulsions of Jacksonian type, motor aphasia, hallucinations of hearing, right facial paralysis, paralysis of the right arm and right hemianopsia. These all disappeared very promptly under intramuscular injections of oil containing biniodide, so that the patient felt and appeared as well and capable as he had ever been.

Scleroderma.—This condition has usually been considered due to disease of the trophic centers in various parts of the nervous system, not only spinal, but also cerebral and bullar. B. Sachs (Phil. Med. Jour., Feb. 8, 1902) advances the suggestion that some functional or organic, or perhaps toxic condition of the system influences these centers. In a like manner whether or not nerve influences be at work, the cause of myxedema is at present attributed to deficient thyroid action. Without claiming any analogy the author directs attention to the resemblance of symptoms between myxedema and the scleroderma and reports on the favorable action of the administration of thyroid gland in the latter condition. He gave the thyroid gland in five well-marked cases in doses of from two to six grains t. i. d. The effects varied and seemed least marked in cases in which the scleroderma appeared to be of neural origin. It was found necessary to increase the dosage until some improvement was noted and then the thyroid could be continued in smaller amounts. One patient was apparently entirely cured, but had to take the drug constantly to prevent recurrence of the symptoms; the others showed improvement in the greater pliability of the skin and in freedom from scaling. A more careful trial is urgently advocated.

Resection of the Sympathetic for Trigeminal Neuralgia.—This operation has effected a cure in eight cases so treated by its originator, G. Cavazzani (Gazz. degli Osped., Jan. 26, 1902), the last case being the subject of this paper. The point of resection was the superior cervical ganglion, and the relief experienced is believed to be due to modification in the nutrition of the Gasserian ganglion by resection of the filaments which connect it with the sympathetic. In none of the cases, whether operation was limited to one ganglion or included a larger portion of the cervical sympathetic chain, were there permanent ill-effects due to destruction of the sympathetic function. The author believes that the success of this method in his personal experience, as well as in the hands of other surgeons, should place it among the classical operations for trigeminal neuralgia.

Sympathectomy in Basedow's Disease.—Animal experimentation has shown that exophthalmos may be induced by irritation of the superior ganglion of the cervical sympathetic; hypertrophy of the thyroid has been attributed to the influence of the middle cervical ganglion. Working upon the theory that Basedow's disease is due to irritation of the cervical sympathetic, D. C. Ballarin and D. C. J. Munoz (Rev. d. Med. y Cir. Pract., Feb. 7, 1902) performed bilateral sympathectomy in a case exhibiting typical symptoms of exophthalmic goiter. The patient is said to have recovered from the operation within fifteen days; convalescence being perfectly uneventful. At the present time, four months after the operation, there is marked decrease in exophthalmos, the eyelids now covering the eyes in sleep, whereas formerly they were widely open, palpitations have ceased, and the pulse has been reduced from 150 to 110 per minute.

Psychoses among Jews.—It is remarkable that all but one of the cases of amaurotic family idiocy so far reported have occurred in Jewish children. Impressed by the large proportion of Jews among his cases of periodical insanity, Pilcz (Ann. Medico-psychologiques, Jan.-Feb., 1902) was led to take up the study of mental diseases among Jews in general. From a review of the literature he cites the following: Kraepelin states that the Jews are more prone to mental and nervous diseases than are the Germans, explaining this fact as being probably due to the greater frequency of consanguineous marriages among the former, this view being concurred in by Kirchhoff and Krafft-Ebing. Hirshl found 20 Jews among 100 cases of paralysis. Beadles found a large and abnormal proportion of Jews among his cases of general paralysis (21 per cent.), these figures relating only to males, no difference in this respect being found among females. From his own observation of the cases in the psychiatric clinic at Vienna, Pilcz cites the following statistics: Among 1,219 cases submitted 134 were Jews, a proportion of 10.9 per cent. The Jews form 8.8 per cent. of the general population of Vienna. These figures prove the excessive proportion of Jews among psychiatrical patients, at least so far as Vienna is concerned. Although alcoholism formed the larger proportion of all the cases, reaching the number of 173, not a single case was found among Jews. These also form no pre-

ponderance in cases of dementia, although in dementia secondary to acute psychoses a marked preponderance was found in Jewesses, while in precocious dementia Jews furnished an excessive proportion of cases. From these facts he draws the conclusion that so far as the psychoses incipient at an early age are concerned Jews are in greater danger of becoming dements than are people of other races. Few Jews are observed among cases of moral insanity. All the psychoses of which Jews show the largest proportion of cases are those in which the congenital psychopathic constitution, the so-called "heredito-degenerative" type, forms the principal etiological factor. The large proportion of cases of progressive general paralysis found in Jews leads the author to speculate that the "struggle for existence" among this nationality is the principal etiological factor. There was no difference to be observed between Jews and other people in cases in which the etiology includes causes such as hetero and auto-intoxications, vessel changes, and cerebral lesions.

Relation of Syphilis to Diseases of the Spinal Cord.—In a study of this subject R. V. F. Mohedano (Rev. d. Esp. Med., Year V., No. 63, 1902) reaches the following conclusions: That which gives syphilis a special character as an etiological factor is its indefinite duration, causing it to act not only through the production of local lesions, but as a chronic intoxication. (2) Syphilis may attack any of the organs, but it shows marked predilection for the nervous system. (3) It is not possible through pathological anatomy, symptomatology or time of appearance to separate precisely syphilitic diseases from those known as parasyphilitic. (4) Not all cases of myelitis in individuals who have suffered from syphilis are necessarily of syphilitic origin; neither does the existence of syphilis preclude the possibility of other causes acting. (5) Syphilitic myelitis may appear at any time after infection. (6) The gravity of the infection does not always bear direct relation to the frequency and gravity of medullary affections. (7) The only lesion which can be considered characteristic of syphilitic myelitis is gummatous infiltration, either circumscribed or diffuse. (8) Syphilis may affect simultaneously or successively various parts of the central nervous system. (9) Medullary lesions rarely remain limited, the meninges almost always becoming involved. (10) Medullary syphilis does not present any special symptomatic picture, but may give rise to any medullary syndrome. (11) The diagnosis is based mainly upon a syphilitic history. (12) Syphilis is the most frequent though not the only cause of tabes; there is nothing to justify the belief that ataxia is always of syphilitic origin. (13) The syphilitic nature of an affection should not be judged by the effects of antisyphilitic treatment.

PATHOLOGY AND BACTERIOLOGY.

Snake Venom and the Blood.—A research has just appeared from the Laboratory of the University of Pennsylvania upon "Snake Venom in Relation to Hemolysis, Bacteriolysis, and Toxicity" (Flexner and Noguchi, Univ. of Penna. Med. Bull., Feb., 1902) which promises to be of fundamental importance in its therapeutical applications. By hemolysis is meant the solution of the corpuscles, including erythrocytes and leucocytes of the blood. Such solution is produced by certain inorganic substances and also by various complex agents derived from living plants and animals. Of all such agents, the most active are found in the blood of alien animal species; others are the products of cellular activity, such as venom, and certain toxic products of bacterial growth, as tetanolysin, etc.; still others are yielded by some of the higher plants, as "crotin." After admixture of the corpuscles of the blood with any of these agents, the former first run together, or become "agglutinated"; secondarily, they are dissolved and destroyed. These phenomena of agglutination and of lysis, as seen in the blood, have their counterpart in the actions of certain sera upon bacteria as evidenced by the Widal reaction with typhoid bacilli and by the Pfeiffer phenomenon with cholera spirilla. It has recently become possible not only to demonstrate the fundamental similarity of bacteriolysis and of hemolysis, but to provide a chemical explanation of the processes involved. The agglutinating principle, briefly described as "agglutinin," is distinct from the dissolving one. The latter contains two substances, of which one is stable and is the product of immunization—the intermediary body; the other, which is very unstable, is normally present in the body juices and is known as the complement. The union of the intermediary body with the cells (bacterial, blood-cells, etc.) makes it possible for the complement to come into action and produce solution. It is upon the foregoing facts that the experiments of Flexner with various kinds of venom and various species of sera were based. He showed first that the venoms were capable of producing both agglutination and solution of blood-corpuscles. Marked differences in susceptibility to agglutination were observed in comparing various species of animals, and the agglutinating and the lytic powers of the venom were found to be distinct and separable factors. In the experiments directed toward determining its hemolytic powers, it was found to contain several intermediary bodies, each of which was given up in succession when brought into contact with different species of blood-corpuscles. These intermediary bodies showed special affinities, then, for the complements contained in the blood of the respective animals, and lysis resulted. It was found that the agglutinating principle is identical for red and white cells, but that the dissolving principle for leucocytes is distinct from that for the red cells. The most important part of the research was directed toward determining the effects of venom upon the bactericidal properties of blood-serum. The bacteria used were B. typhi, B. coli, and B. anthracis. It was found that all the venoms experimented with, when used in sufficient quantities, destroyed the bactericidal properties of many normal blood-sera. The manner of the destruction consists in the fixation of the serum-complements by the venoms. Upon the intermediary bodies of serum, the venoms have no action. If, therefore, the venom is incapable of uniting with the complement, as in Necturus, the original bactericidal properties remain unaffected by the presence of the venom. Calmette's antivenom was tested, with regard to its restraining action upon venom-hemolysis and venom anti-bacteriolysis. The substance was found to neutralize venom, and to remove both the hemolytic and the anti-bacteriolytic actions therefrom.

Decomposition of Albuminoid Substances in Excessive Fatigue.—The effect of overfatigue upon the body has been considered from various standpoints; A. Mosso demonstrated a poison in the blood of dogs after exhaustive fatigue. C. Jackson (Arch. Ital. d. Biol., Tome xxxvi., Fasc. 3, 190) has studied the effect of overwork upon the urine. Before and after an extended walking tour, the urine of five men, ranging from seventeen to sixty-two years of age, was examined. The most noticeable effect of exhaustion from the journey was a marked increase in the elimination of nitrogen in every case. It is known that a great part of the nitrogen from food ingested is eliminated in the form of urea, this later increasing with nutrition. The nitrogenous increase in the specimens examined could not, however, be attributed to increased nourishment as, in one instance, the journey was made prac-

tically fasting, urea being reduced one-half in consequence. The hypothesis is advanced that excessive fatigue is a pathological condition in which the substances eliminated by the body are not only increased, but changed in such a way as to indicate dissolution of tissue, probably muscular.

Effect of Splenectomy upon the Bile.—An interesting study of this subject through animal experimentation is reported by A. Pugliese (Bull. delle Scienze Med., Year lxxii., Series viii., Vol. 1), the conclusions reached being that the influence of splenic enucleation upon the quantity of bile secreted is not marked, neither does splenectomy modify to any extent the elaboration by the hepatic cells of biliary acids. The most noticeable effect of exsection of the spleen was diminution in the coloring matter of the bile, the author deducing from this fact that an important function of that organ is to accumulate and pass on to the liver, through the portal vein, such material as is necessary to the formation of biliary pigment by the hepatic cells. After removal of the spleen, this material is distributed to other parts of the body, and only reaches the liver in small quantities through the general circulation; hence the diminished elimination of biliary pigment.

Agglutination of Malarial Blood.—This subject is again discussed by D. Lomonaco and L. Panichi (La Riforma Medica, Feb. 12 and 13, 1902), who give the outcome of recent experiments as follows: The serum of malarial subjects gives the same reaction as the blood, conditions of success being that the specimen be obtained by Widal's method of serum diagnosis, *i. e.*, by means of a capillary tube applied to the punctured finger, the serum being allowed to separate naturally, as it does upon standing a few hours, and that the mixture with the normal blood be made drop by drop. If a healthy individual be subjected to bloodletting and the serum separated by centrifuge, agglutination always occurs even if the red cells of the same individual be added. Agglutination is never obtained with the normal specimen when Widal's method is used. In the opinion of the authors, variations in technic account for the fact that the diagnostic value of the agglutination phenomenon has been questioned. It is further observed that quinine does not affect agglutination of normal specimens improperly treated and that in the blood of patients suffering from other infections, whether associated with malaria or not, agglutination persists *in vitro* even when the serum is diluted with strong solutions of quinine. The writers sum up as follows: (1) The blood or serum of a healthy subject mixed with the blood of another healthy subject is non-agglutinating. (2) The serum of a healthy individual acquires agglutinating power if obtained in such manner as to injure the red cells. (3) Addition to malarial blood or serum of an equal volume of an isotonic solution of sodium chloride, containing 1 per cent. of quinine, causes disappearance of the agglutinating phenomenon. (4) This property serves to determine the malarial nature of a given specimen. (5) In malarial serum or blood, so treated, persistence of the agglutination phenomenon indicates the presence of some other infectious process. A further series of experiments was carried out for the purpose of differentiating between agglutination of malarial blood and that of blood in other diseases. For this purpose the blood was diluted with the physiological solution, the degree of dilution causing disappearance of agglutination in each specimen to be noted. In most instances agglutinating power was destroyed after dilution of 1:1; in a few cases typhoid blood showed agglutination after dilution of 1:3 or 1:4. The highest agglutinating power was shown in malarial blood, the phenomenon being observed invariably in dilutions over 1:5. Hence it is concluded that specimens which retain their agglutinating power in dilutions over 1:5 may be considered as malarial.

GENITO-URINARY AND SKIN.

Treatment of Chronic Eczema.—There is no rational therapy of this distressing disorder which does not take into very careful consideration its undoubted staphylococcic origin. While we are not yet in a position to produce proof positive that germs are the causative factor in every case it is at least significant that treatment directed toward destroying germ life in the most potent of cure in the worst and most chronic cases. A. Eddowes (Brit. Med. Jour., Feb. 15, 1902), after dwelling on the very great importance of first carbolizing the skin before applying Unna's zinc gelatin, gives a sort of *vade-mecum* series of pertinent remarks touching on the general principles of treatment. "Is a patch of eczema chronic and dry, we must moisten and grease it. If too wet, we must dry it. If swollen, we must raise and support it; if hot, we must cool it; if painful, we must soothe it; if due primarily to microbes, we must kill or check them. If there be great-cell infiltration, we must excite absorption; if dead scales cover the surfaces and prevent our medicines from acting, we must remove them; if the part is being irritated in any way, it must be protected or all treatment will fail." It is very difficult to draw anything like a sharp distinction between chronic and acute eczema. Granted that the symptoms are due to infection, the treatment in the acute condition will not vary much from that of chronic stages. It must not be forgotten, however, that there are in many cases associated causes and complications, such as constipation, dyspepsia, gout, tubercle, urticaria, syphilis, and that the case may be gravely aggravated by sunlight, heat, cold winds, wet, plants, discharges of one kind or another, and scabies. The internal remedies may be summed up as follows: Gray powder, calomel, aloes, citrates and carbonates, iron, quinine, strychnine, occasionally colchicum, and still more rarely arsenic—these will be all one needs. In many cases the diet is all-important. This is particularly true of children; often the addition of meat-juice or cod-liver oil will work wonders and frequently thyroid extract is all that is required. In fine, then, in all cases the parts should be carbolized before Unna's paste or any other protective is applied; generally the accompanying constitutional treatment should be decided upon almost exclusively by the history of the case.

Operations upon the Prostate.—In order that the best results may be obtained from operations upon enlarged prostates, it is necessary to understand the particular indications which each operation meets, for it is impossible to cure or even improve every case by a particular routine method. The five different procedures at present in favor with the profession, according to E. H. Fenwick (Practitioner, Feb., 1902), are: (1) resection of one or both vasa deferentia; (2) removal of one or both testes (orchidectomy); (3) division of the prostate at the urethral opening through perineal section; (4) division of prostate by an electrocautery knife passed along the urethra (Bottini); (5) removal or enucleation of obstructing parts of prostate by perineal or suprapubic section. Each one of these operations has its particular effect and hence it is necessary to first find out the shape, size and form of the obstructing organ. The result of a vasectomy is similar to that of an orchidectomy, but very much less pronounced. The prostatic lobes in health correspond in functional activity with the testes, and hence abrogation of the function of the latter causes a shrinking of the prostate, but it is not general atrophy as many suppose. The prostatic lobe corresponding to an absent testicle usually

becomes broader and flatter than the other, the lobe becomes firmer and when both testicles are removed the sulcus between the prostatic lobes becomes deeper, corresponding to an atrophy of the verumontanum and structures around the urethra, the function of which depends upon the preservation of the sexual act. The median lobe is seldom affected by this procedure. In the median lobe group of cases the hypertrophy may be due to fibrous or adenomatous growths, but in either case a suprapubic cystotomy is usually the best method, and in the adenomatous variety the growth can be easily shelled out. In the fibrous variety the lobe must be removed preferably by the flap operation. There is a group of cases in which the only obstruction is in the form of a projecting bar or collar at the orifice of the urethra, the canal being otherwise free. The gland is only moderately enlarged, but very firm or even hard. The interlobar fissure is very slight or filled up by a ridge of fibrous tissue which denotes an "iron-bound" gland unsuited for perineal or suprapubic enucleation. A beginning hard cancer of the prostate is sometimes mistaken for a gland of this variety. These dense prostates are best treated by a median perineal section, dividing the fibrous collar, up to the neck of the bladder. In the adenomatous variety rectal examination shows a huge elastic prostate projecting backward, with a sulcus almost obliterated to a line by intraprostatic tension, and in addition a distorted lengthened prostatic urethra. Enucleation is distinctly indicated in these cases and can usually be easily done either by the perineal or by the suprapubic route, the latter being preferred by most surgeons, unless the patient is very weak. Only about 50 per cent. of prostates are of this nature, however, and hence enucleation can be performed in only about one-half of the cases. In short, there are two essential groups of general enlargement of the prostate—the small, tough, flat, unshellable prostate, which generally has a filled-up sulcus, and the large, soft, elastic, projecting, shellable prostate, which has a fine line of sulcus.

Perineal Prostatectomy.—An operation which avoids injury to the bladder and is applicable to all forms of prostatic enlargement is proposed by A. H. Ferguson (Jour. Amer. Med. Assoc., Feb. 22, 1902) who reports good results in six cases. The prostate is exposed by a median perineal incision and the capsule is opened transversely. The gland is enucleated with the finger and removed piecemeal by special forceps, no effort being made to save the posterior portion of the prostatic urethra. A gauze-covered drainage-tube is introduced into the bladder, after the latter has been flushed out, and is allowed to project from the partially-sutured perineal wound. The author claims that this method affords the most direct route to the prostate and avoids injury of the bladder or surrounding parts. By working within the capsule hemorrhage is avoided. Perineal drainage is more complete and danger from septicemia is not as prominent as in the suprapubic operation. Uremia is less likely on account of the short anesthesia and there is less accompanying shock.

Treatment of Gonorrhea.—The treatment of gonorrhea has recently been subjected to such an upheaval, especially by Guyon and his school, that general practitioners are apt to ask themselves whether they are really up-to-date with their older and less radical methods of cure. The entire question has been reviewed with much fairness and sanity by Heaton (Birmingham Med. Rev., Feb., 1902), who has had a wide experience. As regards acute gonorrhea, he condemns the so-called abortive treatment by means of the injection of a solution of nitrate of silver of gr. xv. or xx. to ℥i. The disease frequently fails to abort within the promised fourteen days. In fact, the gonorrhea often pursues its course unchecked, or the acute symptoms may even be accelerated and intensified. Moreover, there is risk of urethral and of periurethral abscesses, and of secondary strictures. Systematic treatment and very frequent irrigations of the anterior urethra during the early stages with mild antiseptics are also discarded as too tedious and laborious. The general treatment in acute cases is of great importance. In so far as possible, absolute physical rest should be enjoined. The patient should be kept on a reasonably low diet and fluids should be given in considerable quantity. Hot hip-baths are of great service. Both penis and scrotum are to be supported by bandages. Free exit must be given to the urethral secretions, and the glans penis must be bathed at least twice daily to keep it clean. The drug treatment is symptomatic in the early stages. The oleoresins at this stage only do harm. A brisk purge to relieve the bowels, aconite if constitutional disturbance be prominent, alkalies and hyoscyamus to soothe the mucous membrane of the urethra, will fulfil most of the requirements. When the discharge is profuse, some very mild antiseptic mixed with an anodyne is to be used as an injection to wash out the inflamed canal; one to two drams of the fluid are to be injected, without the use of any force, and to be retained for one or two minutes. As the acute stage subsides and during the whole of the stage of gleet the various oleoresins form the sheet anchor as internal medicines. Sandal-wood is the most efficacious and least likely to disturb digestion; it is best given in capsules. Cubeb is especially useful in the more chronic cases. At the same stage of the disease, which is marked by a comparative thinness of the discharge and by a decrease in the ardor urinæ, the local treatment is altered. Astringent solutions are now indicated. The most useful of these is permanganate of zinc in a strength of gr. ⅛, increased to gr. ½, to ℥i. The other sulphates, also protargol, are likewise valuable. The great majority of cases of acute gonorrhea may be cured by these means within from four to five weeks. Those which persist and those which reach the practitioner after years of neglect fall into the category of chronic gleet and require an absolutely different plan of treatment. The persistence of the disease may be due either to trouble within the anterior urethra, such as an unhealthy condition of its entire mucosa, or a slight stricture with ulceration behind it, or "granular patches," or to trouble posteriorly, such as inflammation or abscess of the deep lacunæ or ducts, or chronic inflammation of the prostate. The use of the cold metal bougie often exerts a marked beneficial effect upon the chronically-inflamed anterior urethra. Local patches are diagnosed by the use of the endoscope, and are treated by direct applications of strong solutions of silver nitrate, gr. xv. or xxx. to ℥i., or protargol, 5 to 20 per cent., made twice or three times weekly. If the trouble lie in the posterior urethra or in the prostate, it is very likely to prove extremely obstinate. The use of the cold metal sound, the daily use of medicated urethral bougies introduced into the deeper portion of the urethra, the instillation of a few drops of some strong astringent by means of a special deep syringe, the daily use of large quantities of some mild astringent introduced under pressure—all these are measures which must be successively and patiently tried, perhaps only to fail.

THERAPEUTICS.

Quinine as a Dressing.—Quinine has been used in lotion for various diseases, but combined with cod-liver oil externally it seems to be a new remedy, according to J. Read (Lancet, Feb. 15, 1902). He employs it with good results, one dram of quinine to eight

ounces of cod-liver oil, to be shaken well before being used, in tertiary and rheumatic ulcers of the leg and for ordinary ulcers, gangrene of the skin, burns in which large surfaces have sloughed away, and other allied conditions. All wounds take on a healthy and kindly action and pus from the surface smells sweet and contains a limited number of germs. There is nothing to recommend the preparation in the way of cheapness or odor, but it has the advantage of supplying a weakened system with an oily food and a tonic drug. For intertrigo its effects are good, if not too long continued. For eczema it does not act well, unless at the same time gastric troubles are corrected.

Injection Treatment of Tuberculosis.—The intravenous injection of sodium cinnamate in the treatment of tuberculosis is again receiving considerable attention. The method is usually only applicable to early cases, and in the words of its originator, Landerer, the whole process may be summed up by saying that the treatment substitutes, by the resulting marked leucocytosis, an active aseptic inflammation for an inactive one and the issue is rapid cicatrization. A. Mann (Phil. Med. Jour., Mch. 1, 1902) submits a report on the progress of cases formerly treated and gives the results of further experience. Of ten cases, two mild ones are apparently entirely cured, and of the other rather severer ones only one (with tuberculous laryngitis) is hopeless, the others all holding their own and even showing some improvement. Seven new cases are reported, four patients, with moderate involvement of the apices, showed an almost entire absence of physical signs and marked gain in weight and condition. Another in whom the process had been present for twenty years, with signs of a large cavity showed unmistakable improvement, with diminution of symptoms, although the cavity has persisted. A patient with infiltration of both lungs, numerous hemorrhages, etc., had an intercurrent attack of smallpox during the treatment, which, judging from the sudden amelioration of symptoms, may have destroyed the virulence of the tuberculous poison. A final case with extensive tuberculous lymphadenitis showed great improvement after two months' treatment. It is to be noted that although the climatic conditions (Denver) may have had a favorable influence, the improvement continued after patients had returned to their homes.

Milk Alimentation in Adults.—Most ancient of all known foods and remedies, milk has in the past thirty years become more and more the regimen of invalids according to the wide testimony of our hospitals. R. Lepine (La Sem. Méd., Fed. 19, 1902), in discussing the practicability of using it in the adult, turns first to a discussion of its composition. Per thousand grams it yields from 110 to 135 grams of dry material. The fat varies according to the animal from which it is drawn; under certain conditions of favorable feeding it may reach 70 grams, goat's milk is much higher than this. Lactose, which in the intestine breaks up into glucose and galactose, averages from 37 to 55 grams per liter. It is noticeable that milk is particularly rich in phosphorus; this varies from 25 to 55 grams per liter. Aside from these well-known constituents there are one or more ferments capable of an automodifying action which affect the caseine to a very considerable extent. Citric acid is another factor not to be classed among the ordinarily recognized ingredients. Can milk, in its purest form, be considered suitable food for an adult? Surely not, for the adult stomach under normal conditions will not digest it as well as the stomach of an infant. The non-absorption, however, of a notable fraction of the albuminoids and of the fat of milk is not its only defect; the lack of stimulation to the nervous system is a more important factor. "Life," said an old master, "is entirely dependent upon excitement." If this proposition were exactly true, milk could not sustain life. These are some of the defects in milk; happily, however, they are no serious disadvantage in its use in certain diseases. Among the more important of these should be named the disorders of the digestive tract, particularly round ulcers of the stomach, albeit there are certain conditions of the rectum in which milk alimentation gives as good results as in gastric ulcer. In many of the diseases of the liver, milk is admirable, particularly in the treatment of catarrhal jaundice, in which it is said by some to be almost curative. In Bright's disease, because it gives rise to but few toxins and because of its great diuretic power, it is of perhaps greater value than in any other disease. In febrile disorders, it has long constituted the chief food. Depending upon the fact that it nourishes without exciting, milk has an admirable use in many nervous diseases. In diabetes, if one believes Dongkin, who places his patients upon an exclusive diet of skimmed milk and gets good results, it would seem to be indicated, but since each liter of milk gives only 650 calories of heat, 6 liters, which is the amount prescribed by him, must yield 2,400, which is altogether too little for a diabetic. It is probable that the good results noted in these cases are only apparent.

EYE, EAR, NOSE, AND THROAT.

Chronic Progressive Deafness.—This form of deafness occurs quite insidiously without warning, pain or discomfort, and is apparent to the individual only after a marked impairment of hearing has taken place. In contradistinction to deafness which is secondary to the diseases of the ear, M. Collier (Medical Press & Circular, Feb. 5, 1902) calls this chronic progressive deafness. The etiology of this affection, like that of most of the affections of the upper respiratory tract, requires for its understanding knowledge of the laws of physics and pneumatics. It is too often found that ordinary writers through ignorance of the subject really deny that the tension of the air in the cavity of the ear must be the same as that of the outside ear in order to insure a free and normal vibration of the drumhead. It is also erroneously contended that obstruction to the free inlet of air to the tympanic cavity produces no difference in the tension of the air within that cavity. Many consider new the theory that if the normal extravascular pressure be diminished in the tympanic cavity the intravascular pressure will assert itself by dilating the tissues and vessels generally under the lessened pressure. An important point which the author makes is that the tympanic cavity is a part of the nose, both anatomically and developmentally. Affections of the nose and the tympanum have a close affinity. Both the tympanic cavity and the other cavities leading from the nose are anatomical parts of and extensions from the nose cavity and any alterations in the physical condition of the bones of the nose cavity will be communicated to and affect the patent extensions from this cavity. Under normal circumstances the contents of each cavity have a free intercommunication. The tension of the air within the nose is the same as the tension of the air within the tympanic cavity and both are the same as that of the air in the surrounding atmosphere. The tubotympanic cavity is a part of the upper air-passages as much as is the antrum or any of the accessory cavities of the nose. It is lined with an extension of the same membrane that lines the nose and is covered with the same sort of ciliated epithelium, but differs in this one respect, that it partakes of the character of, and is virtually, a periosteum. This dif-

ference in the constitution of the lining of the tubo-tympanic cavity greatly increases its importance both physiologically and pathologically. This anatomical continuity between these cavities is the ground upon which all the other causes of middle-ear disease rest. These are so well known as not to need enumeration, and it is necessary to add only that all conditions of the nose and the other accessory cavities of it have a direct bearing upon this form of deafness. The treatment therefore consists in removing at an early date all chronic conditions of the nose and its appendages, in the effort to cure or to prevent chronic progressive deafness.

Eye Defects and Mental Dulness.—By far the most frequent defects of the eye which may cause apparent mental dulness and deficiency in children, writes C. S. BULL (Pediatrics, Feb. 15, 1902), are anomalies of refraction. In the order of frequency, though not of importance, these are hypermetropia, astigmatism and myopia. The subject of the first may be dull and stupid, because the eye-strain renders him incapable of any sustained mental effort. Astigmatism may lead to a train of reflexes such as will handicap a child seriously. The myopic child may not see the blackboard, the maps on the wall, or what is going on in the playground unless he is close by, and his companions jeer at him for his stupidity. This makes him self-conscious and perhaps perverted in his tastes. Insufficiencies of the ocular muscles causing squint produce headache, eyeache and mental confusion, and by application to work these become so marked and constant that the child is no longer capable of continuous mental effort. These children are often unjustly punished for backwardness. The rarer ocular defects causing mental deficiency are congenital cataract, dislocation of the lens, absence of pigment in the uveal tract, especially the iris, coloboma and aniridia. This last exposes the eye to too much light. There is also a congenital want of visual memory, nine cases of which have been recently reported, due to an organic deficiency in the part of the brain where the visual impressions of letters, etc., are registered. These children are quite unable to learn to read.

THERAPEUTIC HINTS.

Rheumatism in Children.—The following is well borne by the stomach, the bitter taste disguising the unpleasant sweetness of the salicylate:

℞ Sodii salicylatis .....gm. 4.0 (℥i)
Liq. potassii citratis ..... 60.0 (℥ij)
Tinct. cardamon. comp.....ad 90.0 (℥iij)
M. Sig. Two teaspoonfuls every two hours for a child five years old.

A useful external application to the joints is:

℞ Ol. gaulther .....c.c. 30.0 (℥i)
Alcohol ..... 15.0 (℥ss)
Lin. chloroformis .....ad 120.0 (℥iv)
M. Sig. Apply externally on cotton.—W. M. POWELL in Diseases of Children.

Nutrient Enema.—A nutrient enema frequently employed at St. Luke's Hospital is:

℞ Yolk of one egg.
Beef peptonoids .....c.c 8.0 (℥ij)
Peptonized milk ..... 180.0 (℥vi)
Whisky ..... 30.0 (℥i)
Sodium chloride .....a pinch

A stimulating enema is

℞ Whisky .....c.c 15.0 (℥ss)
Black coffee .....120.0 (℥iv)

Gall-stones.—Diet, exercise and diluent beverages combine to favor the disappearance of the stone. As a rule, too little water is taken in these cases. Alkaline saline waters stimulate peristalsis and increase the flow of blood to the abdomen, the bile-passages being massaged by the former and the diseased mucous membrane benefiting by the latter. These salines do not dissolve the stones, for such allowed to stand two weeks in a 1-per-cent. solution of sodium salicylate, benzoate, phosphate, sulphate, bicarbonate, or chloride, potassium sulphate or ammonium chloride suffered no loss of weight. Allowed to stand in olive oil, however, a gall-stone lost 68 per cent. of its weight in two days and then disintegrated. The solid matter of a stone becomes viscid in a few hours in a 5-per-cent. solution of animal soap. Large doses of oil, probably do not reach the gall-stone directly, but by producing an increased proportion of fat, fatty acid and soap in the bile, cause it to have a solvent action on the cholesterin of the stone. For this method of treatment from two to ten ounces of oil should be given daily, and the results are very questionable. Massage of the gall-bladder would, in many instances, be useless or harmful. During a gall-stone attack relief is urgently demanded. A pint of water taken as hot as possible, with hot fomentations over the liver, may give relief, or c.c. 1.0 (♏xv) of spiritus etheris in two teaspoonfuls of chloroform-water every quarter of an hour. Exalgine, gm. 0.06 (gr. i), every half-hour for three or four doses is also of service. These failing, morphine must be used.—Mayo Robson in Allbutt's System of Medicine.

General Septic Peritonitis.—Formerly, in these cases, G. E. ARMSTRONG (Montreal Med. Jour., Feb., 1902) withheld opium and endeavored to secure free movements of the bowels. The plan which he has adopted of late, however, is to arrest peristalsis and promote the elimination of poisons by stomach lavage, rectal feeding entirely replacing stomach feeding, and the administration of opium or morphine hypodermically. The use of this latter before surgical intervention should be strongly condemned, because, of course, the initial cause of the peritonitis must be attacked by operation. Stomach lavage promotes better breathing and lessens vomiting and peristalsis. The author also advocates more frequent operation under local anesthesia in these cases.

Uncontrollable Vomiting.—The following treatment is especially adapted to the vomiting of pregnancy, though it may be used in emesis from other causes:

℞ Cocaine hydrochlorate ..... .10 (gr. ij)
Antipyrin ..... 1.00 (gr. xv)
Distilled water ..... 100.00 (℥iiiss)
Sig. A teaspoonful every half hour.
Or:
℞ Cocaine hydrochlorate ..... .50 (gr. viij)
Distilled water .....50.00 (℥iss)

Sig. Six drops, repeat in one hour, then in three hours if necessary; after this reduce to three or four drops before meals. For local application by means of tampon to cervix in vomiting of pregnancy or of acute metritis:

Cocaine hydrochlorate ..... 1.00 (gr. xv)
Ext. belladonna ..... .25 (gr. iv)
Vaseline .....10.00 (℥iiss)

Upon the theory that vomiting of pregnancy may be due to general intoxication of the system, Condamin suggests injection, preferably rectal, of artificial serum, three to four liters daily; 300 grams being slowly injected at one time. If peristalsis be excited, the injection should be suspended and resumed later. In cases of great intolerance a few drops of laudanum may be added. For nourishment LUTAUD advises plasmon, beginning with a teaspoonful after each dose of cocaine.—Jour. d. Med. d. Paris, Feb. 23, 1902.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, MARCH 29, 1902.

THE EVOLUTION OF TYPHOID NOSOLOGY.

Time was, and not so many years ago, when typhoid fever was considered to be a febrile disease the specific anatomical basis of which was an ulceration of the intestines. The systemic symptoms of the disease were looked upon as due to the absorption of toxic materials from the bowels. At first these toxic materials were thought to owe their origin to chemical substances produced by the breaking down of the intestinal ulcers, hence the apathetic state of the patient during the third week of the disease when the ulcerative process reached its climax. Later came the idea that toxic substances which caused the general symptoms were produced during the growth of the specific bacteria of the disease. In recent years as the result mainly of bacteriological investigations there has come the realization that the pathologico-anatomical basis of the disease is most frequently, though by no means necessarily, located in the intestines. Extra-intestinal typhoid fever is no longer a theory, but a demonstrated fact. The biliary tract, the lungs and the meninges are especially liable to invasion by typhoid bacilli, and the bacilli may fail to affect any other tissues except these. Bacteriological investigations and especially of late the Widal reaction have demonstrated that many anomalous febrile conditions utterly unsuspected before of being typhoid in origin are really due to the presence of the bacillus of Eberth.

For many years it was thought that typhoid fever was rare in children under five years of age. Some ten years ago a distinguished specialist in children's diseases insisted that the disease was so rare during these early years as to be justifiably excluded at once when a question of doubtful diagnosis in children's febrile affections was under consideration. The use of the Widal test as shown by the series of cases reported from Mt. Sinai Hospital (see page 588) demonstrates not only that typhoid fever is not rare in children, but that it is quite as frequent during the first five years of life, considering the opportunities for infection at this time, as during any corresponding subsequent period. The most interesting observation with regard to typhoid fever in very young children is that the disease runs, as a rule, an anomalous and often extremely atypical course. It is evident that in most cases its true nature remains unrecognized.

Typhoid fever in the early years may, for instance, simulate lobar pneumonia so completely as to present no symptoms beyond those found in the respiratory tract, symptoms indicative only of a process of pulmonary consolidation which clears up not by crisis, but by lysis, and this is of course not unusual, even in the ordinary pneumonia of children. A classical picture of meningitis may be the result of meningeal invasion by the typhoid bacillus, no symptom pointing to any localization of the bacilli or their products in any other part of the body. The most difficult diagnoses occur, however, in cases of acute intestinal disturbance with more or less continued fever. In these patients the fever is set down as due to intestinal irritation, while its irregularity is supposed to exclude all necessity for thinking of typhoid. During the season of maximal prevalence of typhoid fever many cases presenting symptoms ordinarily quite distinct from this disease will prove if submitted to the Widal test to be true cases of typhoid fever, according to our present knowledge of the disease.

This is also true of certain cases in adults in which there is very little ground for the clinical diagnosis of typhoid fever. On the other hand, certain clinically typical cases of typhoid fail to give the Widal reaction. Dr. Ewing in his important paper on "Serumtherapy in Typhoid Fever" (see page 577) attributes this peculiarity to the fact that not even all the types of clinical typhoid fever are due to the

same form of typhoid bacillus. The serum of a patient suffering from any given form of typhoid fever produces its most characteristic reaction only with cultures of the species of bacillus which has produced the fever. The variations in typhoid bacilli are well known: hence the different degrees of success of the Widal reaction. A corresponding state of affairs exists with regard to the therapeutic action of streptococcus serum. Antistreptococcus serum has a beneficial effect only in cases in which it is prepared from exactly the same variety of streptococcus as produces the pathological condition to be treated. The number of differing streptococci is legion; hence the dissatisfaction with this remedy. Long ago it was shown that if lesions were produced in the ears of rabbits by the injection of different cultures of streptococci, one set of lesions might be rapidly cured by the subcutaneous administration of antistreptococcus serum, while the set of lesions in the other ear, absolutely uninfluenced by the remedy, continued their course as before.

The Widal test has proved its usefulness as a diagnostic aid. It has not proved to be all that was at first claimed for it: more especially at the beginning of typhoid fever when some pathognomonic sign would be of the greatest service. Widal's work, however, and the general introduction of the test throughout the world promises to be of special service in opening up new vistas in our knowledge of typhoid fever. There is good reason to hope that the recognition of various types of typhoid fever will become possible and that the prognosis of the disease, as regards the possibility of its abortion and the probability of a relapse in any given case, will become more assured. No single advance in medicine can be judged by itself, but by its influence upon cognate truths. In its suggestive value for further investigation the Widal test has been very rich. Its employment and the critical adjudication of its results promise a new era in our knowledge of an extremely important department of medicine.

PRACTICAL POINTS ON THE DYNAMICS OF LIFE.

Professor Loeb of the University of Chicago has been delivering at Columbia University during the past two weeks a series of ten lectures on the Dynamics of Life. As Dr. Loeb's work in biology is attracting much attention, popular as well as scientific, it is almost needless to say that the lectures gave in scientific terms the results of simple but suggestive scientific investigation, and the last thing that could be thought of was any attempt to make his conclusions have a wider application, or his observations a more far-reaching significance than was justified by the actual facts.

Certain of the recent biological advances have a special interest for medical men because they touch more or less nearly on topics of practical medical import. For instance, it has long been one of the mysteries of pharmacology that the natural mineral waters seem to be able to accomplish results that the best possible imitations of them do not affect. This mystery has attracted no little attention. Professor Liebreich in Berlin suggested that it was possible we did not as yet, notwithstanding all our presumed accuracy and completeness of analysis, know the definite composition of the ingredients of mineral waters. He pointed to the comparatively recent discovery of argon in the air as an example of the possibilities of analytic discovery that exist in even the most familiar substances. Dr. Loeb presents some suggestive thoughts that have a possible bearing on this subject. It was found that the eggs of certain minute marine creatures fail to develop if a single one of the ingredients in their native sea-water has been removed. It matters not which one of the ingredients is lacking the result is the same, while the eggs will nevertheless develop in distilled water. It is as if a certain equilibrium of chemical affinities or, as Professor Loeb prefers to call it, of ionization, existed in normal sea-water, which favored development of the eggs, while any disturbance of this equilibrium acted to inhibit such development. The application of this idea to the problem of the therapeutics of mineral waters is obvious.

Professor Loeb is prone to consider most of the metabolic processes carried on by the fluids of the body as really electrical in character. It is not so much the atoms of salts in solution that exert an influence upon tissues as the electrical charges the atoms bear and which act and react upon oppositely charged particles. These atoms bearing each an electrical charge are the ions of the newer physico-chemical physiology. In the now well-known phrase of Arrhenius, "It is the ions that act," and Professor Loeb's work has consisted mainly of the application of the ideas of Van t' Hoff, Arrhenius and Ostwald, especially of the latter, to physiology.

Under these circumstances it might have been expected that he would foresee a great future for electric therapeutics. On the contrary, his opinion is most pessimistic with regard to the possible benefits to be derived from any form of electrical treatment. In the oscillatory waves of electricity

of high potential introduced into medicine some years ago by D'Arsonval and that raised such high hopes because they seemed to be possessed of so much latent energy, Professor Loeb sees especially little to hope for. They actually produce no physiological effect because we are protected from them by our epidermis as by an impermeable screen. The X-rays alone seem to have some promise in them, although this is as much perhaps because of the accompanying light as of the electric radiations. For Professor Loeb sees a large future in light as a therapeutic agent. There is no form of living protaplasm that at some period of its existence is not very seriously affected by light and luminous radiations have a penetrating power and a dirigibility that make them very promising for future therapeusis.

There are certain points in which Professor Loeb differs completely from his colleague at Chicago, Professor Matthews. The latter asserts that cathelectrotonus may be due to the coagulation of material that takes place at the cathode when a muscle is stimulated. The facts, however, fail to justify any such conclusion. Coagulation is a slow process requiring enormous currents, comparatively speaking, to bring it about, while the phenomena of electrotonus and cathelectrotonus are rapidly developed and require but small currents. It is unfortunate that we are reminded in this connection of some of our friends, the newspapers, who print a rumor to-day and make a news item of its correction to-morrow. We are scarcely to expect such battledore with presumably scientific truths at a great university. On the whole Professor Loeb's review of the newer physiology founded on the recent physical chemistry, as the Germans call it, has proved not only interesting but eminently suggestive. More than this, however, can scarcely be said of it. Much of the present widely-gleaned information will have to be carefully winnowed before it will come into the garner as scientific truth. Many of the apparently suggestive practical hints will prove utterly fallacious. There is a justifiable pride, however, in thinking that this original work of the very highest order is being accomplished here in America, and it remains as a simple duty to see that it shall not be sensationally vulgarized before its true import is recognized.

QUACKS IN GERMANY.

According to recent Berlin police reports nowhere in the world have quacks and their nostrums more support than in Germany. While the city population of Germany has increased 58 per cent. and the regular medical men 76 per cent., the quacks have increased 1,537 per cent. Of 123 men who were found to practise medicine in Berlin without a license 30 had been domestics, 45 artisans, and 16 clerks. Only 24 had even a fair education. The women quacks were more numerous than men quacks. Of 130 found practising without a license only one was even fairly well educated. Sixty had been servant girls, 24 dressmakers, 10 charwomen and five nurses. The three men who made the largest incomes had been clerks; of the three most prosperous women two had been washerwomen and one a milliner. Thirty per cent. of the men and 15 per cent. of the women had been in jail.

Considering the quackish performances of men in high station and the appointment by Bismarck of antifat quacks to medical positions in the universities, this increase in German quackery is not surprising. Considering, also, the attempt by theologians to obtain control of medical institutions, insane hospitals, etc., popular tendency to quackery is naturally increased. Among a certain large proportion of the German agricultural population and the lower middle class, there is a strong tendency to mysticism and this always tends to the occult, of which the quack is a representative. Despite all the sacrifices of personal liberty which Germany has made to secure paternalism, it is obvious that regulation of quackery is as ineffectual there as in the United States.

ECHOES AND NEWS.

NEW YORK.

The Spitting Nuisance in New York.—The anti-spitting crusade has been very active within the past few weeks. Last week over fifty expectorators were arrested and of these thirty-two were each fined $5.00.

Eastern Medical Society.—The Eastern Medical Society of New York City held its annual dinner at the Broadway Central Hotel Saturday evening, March 22d. The attendance was the largest in the Society's history. After the dinner was served the following toasts were responded to: "Man and Mind," by Rev. Dr. G. Gottheil; "Our Specialties," by Dr. Emil Gruening; "Our Hospitals," by Dr. Arpad G. Gerster; "Our Sister Societies," by Dr. Parker Syms; "Our Own Society," by Dr. R. Abrahams.

Work of the Babies' Hospital.—The annual report of the Babies' Hospital for the past year shows that only $450.55 was paid for board of patients during that time. A training-school for nurse maids has been established in connection with the hospital. A six-months' course is necessary and after the maids have finished this they are kept under the observation of the hospital authorities; so competent nurses for young children may always be had there. The hospital has

treated in the eleven years since it was founded 32,000 patients. The new hospital now being built at Lexington Avenue and Fifty-fifth Street is to be a seven-story, fireproof building. There will be five wards, accommodating fifty patients, besides the nurses and officers. All the branches of the hospital will be located in this building.

Hospital Funds Distributed.—The Saturday and Sunday Association has this year collected nearly eighty thousand dollars. During the present week its committee has apportioned the major part of this amount among thirty-eight local hospitals on the basis of the free work done by each. The first six on the list are as follows: Montefiore Home, $6,600; St. Luke's Hospital, $6,038.05; Mt. Sinai Hospital, $5,351.55; Roosevelt Hospital, $4,346.31; German Hospital, $3,823.94; Ruptured & Crippled, $3,504.91.

PHILADELPHIA.

Smallpox and Typhoid Fever Abating.—For the week ending March 22d, there were reported thirty-five new cases of smallpox with three deaths and sixty new cases of typhoid fever with eleven deaths. This is the smallest number of deaths from these two diseases for any one week since 1900. There are now 219 cases of smallpox under treatment.

Charity Ball Receipts.—Each of the four beneficiaries will receive $2,850 as its share of the proceeds of the twenty-second annual Charity Ball held last month. The recipients this year are the children's wards of the University of Pennsylvania and Jefferson Medical College Hospitals, the Rush Hospital for Consumption and Allied Diseases, and St. Timothy's Memorial Hospital and House of Mercy, Roxborough.

Obituary.—Dr. Gerhard Loeling, who had practised in the northern section of the city for nearly thirty years, died suddenly of heart disease, March 23d, aged sixty-nine years. Dr. Loeling was born in Prussia, his father being an eminent surgeon of that country.—The body of Dr. Harry Whitesell, of Sewickley, was found March 23d, resting on a ledge of rock on the Ohio River bank, he having been killed by a fall, while making a night call on a patient.

Vacancy at Polyclinic Filled.—Dr. J. Alison Scott has been elected professor of clinical medicine and therapeutics in the Philadelphia Polyclinic to succeed Dr. S. Solis Cohen who resigned a short time since. Dr. Scott, who graduated from the University of Pennsylvania in 1889, is instructor in clinical medicine at the University and physician to the Pennsylvania Hospital and to the Church Home for Children.

Reception to Dr. Wyeth.—The Medical Club of Philadelphia will give a reception at the Hotel Bellevue on the evening of April 5th in honor of Dr. John A. Wyeth of New York City.

Training-School for Crippled Children.—Work is to be at once begun on the buildings of the Widener Memorial Training-School for Crippled Children at Logan. The plans provide for a three-story main, or administration building, 42 by 84 feet in size, with side wings 72 by 34 feet each. In addition to this will be an educational building, an industrial building, and two cottages, each 88 by 45 feet in size. The children will receive instruction in physical, manual, and mental training. Provision for medical and surgical treatment will be made by the inclusion of wards in the buildings. The donor, Mr. P. A. B. Widener, who erects the institution as a memorial to his wife, has stated it to be a home, hospital, and school for crippled children, where they can be cared for if helpless, receive such medical or surgical aid as shall be necessary and, in addition to a general education, receive instruction in such industrial pursuits as will assist them to become self-supporting. The entire cost of the institution, including endowments, will be about $2,000,000. Dr. De Forrest Willard will have general charge.

A New Operation for the Cure of Cystocele.—At the meeting of the Section on Gynecology of the College of Physicians, March 20th, Dr. Barton Cooke Hirst detailed a method of correcting cystocele, which he has been employing during the past few months. Dr. Hirst stated that repair of the anterior vaginal wall was much more difficult than that of the posterior wall or of the cervix. For the two latter there are well-recognized and satisfactory operations, but for the former there is no one method that will cure. There may be two elements entering into a tear of the anterior vaginal wall; (1) The wall is torn loose from the subjacent tissues, and (2) there is a tear of the transverse muscle which extends from the ischium to the pubis and which has an attachment to the anterior vaginal wall. This muscle is frequently torn and any operation which does not recognize this element is not a complete one. If the wall alone be united the muscular support is lacking. If the ends of the muscle alone be united there will still be a bagging of the other tissues. The operator must recognize both. In addition to denuding a central area Dr. Hirst displays the anterior vaginal sulcus of one side by means of three bullet forceps, the triangular area thus mapped out being also denuded. The opposite sulcus is then treated in like manner, although the tear is usually only on the left side. The denuded areas are then closed by sutures, the buried tier suture being preferred. The statement was made that time must elapse, probably ten years, before the real status of this operation could be determined from observation of the cases on whom it is being used. Dr. Hirst also stated that an anterior operation is needed in the great majority of cases in which the posterior is done, it being a false notion that the anterior vaginal wall is supported by the posterior.

CANADA.

A Canadian Honored in the Philippines.—A little over a year ago Dr. Harry J. Watson, a graduate of Trinity Medical College, 1896, who was then practising at Ottumwa, Iowa, was appointed to the United States Army Medical Service in the Philippines. He has just been appointed chief of the Medical Department of the largest Brigade Hospital in the Philippines. Considering the fact that there are over 475 doctors on the active service list in these Islands, Dr. Watson may be considered to have gained a high honor. It is understood also that Dr. Watson's superior officers have recommended him for a "majority" for distinguished service in the presence of the enemy.

Arts Degree for Medicals at Toronto University.—Arrangements have just been made by the Senate of Toronto University whereby candidates can secure a degree in arts in four years and then go on and secure a degree in medicine in an additional two years. The subject of anatomy will be introduced as an option in the third and fourth years in arts. In this way a student will be enabled at the end of his fourth year in arts to proceed directly to his third year in medicine.

Alleged Blackmailer Pleads Guilty.—A short time ago in Toronto a man endeavored to extort money from two physicians who had been called in to attend his wife and child, respectively. The case came up in the Sessions last week and the very slim defence put up by the defendant soon collapsed, when he pleaded guilty to the charge. Sentence will be pronounced next week.

Obituaries.—Dr. Theodule Bolduc, Montreal, an ex-house-surgeon of the Notre Dame Hospital, that city, died suddenly from heart disease on the afternoon of March 20th. The deceased was only twenty-six years of age, and had only recently commenced the practice of his profession.—Dr. A. Dixon Wagner, a prominent practitioner of Eastern Ontario, died at Cornwall on February 13th, at the age of fifty-three years. He was a graduate of McGill University.—The death of an old Toronto boy and a graduate of Trinity Medical College occurred at Seattle, Wash., on March 21st, of typhoid fever. Dr. F. H. Thompson was a son of a prominent citizen of Toronto and was one of the officers of the Coast and Geodetic Survey steamer "Patterson." He had spent the last two years in Alaska near Cape Nome and Sitka.

The Canadian Medical Association.—The next annual meeting of this Association will be held at Montreal on September 16, 17 and 18, 1902, under the presidency of Dr. F. J. Shepherd of that city. Dr. George Elliott, Toronto, is the general secretary. The Address in Medicine will be delivered by Professor Osler of Johns Hopkins and the Address in Surgery by Dr. John Stewart of Halifax, Nova Scotia. It is expected that there will be a very large attendance at the Montreal meeting.

The Ontario Medical Association.—This Association will hold its annual meeting in Toronto on June 4th and 5th under the presidency of Dr. N. A. Powell of that city, Dr. Harold C. Parsons of Toronto being the general secretary. Dr. John T. Fotheringham has been appointed chairman of the Committee on Papers and Business. It is understood that there will be several new and interesting features of the 1902 meeting.

The Southern Medical Association of Manitoba.—This Association, which has only lately been formed, met at Brandon on February 26th, over sixty of the leading physicians of the Province being present. President McConnell of Morden occupied the chair, while Dr. J. T. Lamont of Treherne, who has been greatly instrumental in organizing the Association, acted as secretary. The following papers were contributed: "Necessity of Organization in the Medical Profession," by Dr. J. T. Lamont; "The Ethics of the Profession," by Dr. H. P. Elliot, Morden; "Differential Diagnosis of Smallpox," by Dr. James Patterso, Dominion Health Inspector; "Quarantine in Smallpox," by Dr. Macdonald, Brandon; "Christian Science," by Dr. J. R. Jones, Winnipeg; "Gall Stones," by Dr. H. H. Chown, Winnipeg, past-President of the Canadian Medical Association; "Delayed Union and Non-Union of Fractures," by Dr. John Hardie, Morden. In the evening the profession of Brandon tendered the visiting members a banquet. The following officers were elected for the ensuing year: President, Dr. L. M. More, Brandon; Secretary, Dr. Little, Alexander; Executive Council, Dr. Poole, Neepawa, Dr. Goodwin Elkhorn, Dr. Thompson, Douglas; Drs. Macdonald and McDiarmid, Brandon.

GENERAL.

Mosquitoes and Malaria.—The military authorities in Formosa, says the Tokio correspondent of "The (London) Times" are experimenting extensively in order to determine the influence of mosquitoes on malaria. A battalion of soldiers was completely protected from mosquitoes for 161 days during the malarial season. It entirely escaped the disease. An unprotected battalion at the same place had 259 cases of malaria.

American Association of Pathologists and Bacteriologists.—This new society holds its second annual meeting this week at Cleveland. The program is a very interesting one and a full report will appear in the Medical News.

Tri-State Medical Society of Iowa, Illinois and Missouri.—The tenth annual meeting of this society will be held at Chicago on April 3d and 4th, under the presidency of Dr. John C. Murphy of St. Louis. Dr. William B. La Force, Ottumwa, Iowa, is the secretary, and Dr. Emil Ries, Chicago, chairman of the Committee on Arrangements. An interesting program is announced. An abstract of the proceedings will appear in the Medical News.

Death of the Sultan's Physician.—News is received of the death of the Sultan's chief physician, Mavrogeni Pacha, at Constantinople. Born in 1817 of a noble Greek family, he received his medical education in Vienna, and upon his return to his native country soon became one of its most prominent physicians. He was a professor in the Imperial School of Medicine and the author of several scientific works. One of his sons was at one time minister from Turkey at Washington.

An Oculist-Prince.—Duke Carlo Theodore of Bavaria, who is a physician by profession and a specialist in diseases of the eye, a short time since performed his four thousandth operation for cataract.

Cholera in Manila.—The outbreak of cholera does not create alarm. No white person has been stricken with the disease. According to the report, there have been forty-nine cases and thirty-nine deaths. Experts have gone to investigate the five cases at Malolos, just north of Manila, and the two cases at Aparri in Northern Luzon.

Bubonic Plague in California.—At Berkeley just outside of San Francisco a case of plague has been reported.

Summer Session of Medical Department.—The summer session for 1902 of the Medical Department of the University of Michigan will extend from Monday, June 23d, to Friday, August 8th. The courses offered are classified as *special*, designed for graduates and advanced students, for which no credit will be given, and *credit* courses, which duplicate certain portions of the regular curriculum, and on the satisfactory completion of which, credit will be given. No allowance for time will, however, be given for work done in the summer school; a student cannot, therefore, shorten his residence in college by attending one or more summer sessions. In the laboratory and demonstration courses offered, opportunity will be given the student to do the work for himself, under the personal direction of the instructor. He may thus familiarize himself with the apparatus and instruments used in laboratories and in diagnostic work, and become conversant with their uses. The abundant clinical material of the University hospitals will be at the disposal of the instructors offering special clinical courses and will be freely used for diagnostic work, beside instruction and general clinics.

St. Louis Medical Society of Missouri.—At the meeting held March 22, 1902, Dr. Hugo Ehrenfest read a paper on "Conservatism in the Treatment of Inflammatory Affections of the Uterine Adnexa." The program for next week is as follows: "The Operative Treatment of Prostatic Obstruction," by Dr. Bransford Lewis; "The Application of the Cautery by a New Method for the Reduction of Prostatic Obstruction," by Dr. Wm. N. Wishard, of Indianapolis; "Some Phases of Prostatic Surgery," by Dr. J. P. Bryson, and "Perineal Prostatectomy from the Standpoint of the General Surgeon," by Dr. G. W. Broome.

Vanderbilt Hospital Ward.—Everything is now ready to begin work on the Vanderbilt ward of the Newport Hospital, which Mrs. Cornelius Vanderbilt is

to erect as a memorial to her deceased husband. This building, which is to be constructed of limestone similar to that used in "The Breakers," is to be 125 feet long, 40 feet wide at either end and 50 feet wide in the center. It is to be three stories high. The first floor will be for the treatment of out-patients, the second and third floors will be arranged in rooms, with a children's ward on the third floor.

Pure-Food Bill Favored.—The House Committee on Interstate and Foreign Commerce March 24th voted to report the Hepburn Pure-Food Bill, so called, to prevent the adulteration, misbranding, and imitation of foods, beverages, candies, drugs, condiments, etc., and regulating interstate traffic in such goods. The bill was framed by the National Pure-Food Congress, and for some time hearings have been in progress on this and other pure-food measures. To-day the vote was taken, and was practically unanimous for reporting the Hepburn bill.

Obituary.—Dr. John E. Richardson, a prominent Brooklyn physician, died this week at his home, 127 South Oxford Street, of cancer of the neck. He had been undergoing treatment for several months under the direction of Dr. H. B. Delatour, who had used the X-ray. Dr. Richardson was born fifty-one years ago at Albany, and was the son of "Deacon" William Richardson, former President of the Atlantic Avenue Railroad Company. Dr. Richardson received his early education at the Brooklyn Polytechnic Institute and began work as receiving teller in the Broadway Bank. Later he took up the study of medicine, graduated from the College of Physicians and Surgeons in 1877 and spent several years at Vienna and Berlin. He later became an interne of the Brooklyn Hospital. For a number of years he was the chief surgeon of the Long Island Railroad, of the Atlantic Avenue Railroad and of the Brooklyn police. He was a member of the Oxford, Riding and Driving and Crescent Athletic Clubs of Brooklyn. He was a trustee of the Emmanuel Baptist Church.—Dr. George W. Cushing died on Thursday, March 20th, after a brief illness at his home, No. 221 Schermerhorn Street, Brooklyn. He was born in Canada fifty-three years ago, and came to Brooklyn when a boy. He was graduated from the Long Island College Hospital in 1874, and had practised medicine at the Schermerhorn Street address ever since. He was a member of the Kings County Medical Society, the New York State Medical Society and Long Island Council, Royal Arcanum. His wife, whom he married in 1870, died about three years ago. He leaves a son and daughter.

OBITUARY.

W. W. Johnston, M.D.

By the untimely death of Dr. Johnston the District of Columbia has lost its most prominent physician and the profession at large a valued and much honored member.

Dr. Johnston, son of the well-known Dr. George Johnston, of Washington, was born December 28, 1843. He received his education in private schools and in the college of St. John's, Maryland. He graduated from the medical department of the University of Pennsylvania in the year 1865, and spent a year studying at the University of Edinburgh and in Paris. One of his recent papers is a well-merited tribute to his old master, John Hughes Bennett. He also spent some time in the hospitals of New York. Returning to Washington he began practice with his father and soon was recognized as an industrious and energetic student. In 1871 he joined the Faculty of the Columbian University, in which for nearly twenty years he has occupied the chair of medicine. By devotion to both the scientific and practical aspects of his work he became recognized as one of the foremost clinicians of the South, and to a large and important general medical practice he added the cares and responsibilities of a consultant. He inherited the most select practice in the District, and most of the prominent politicians of the community have come under his care. He was an active member of the Association of American Physicians and the Treasurer of the society until two years ago. To its Transactions he contributed some of his most important papers, particularly those on "Typhoid Fever and Malaria" and on the "Geographical Distribution of Typhoid Fever in the United States." Dr. Johnston was one of the best students of dysentery in the country, on which subject he contributed many important articles, the last a complete and fully up-to-date paper in the new edition of Wood's Reference Handbook of the Medical Sciences.

As a teacher he was thorough, painstaking, clear and concise, and was always interested in the welfare of his students.

As a practitioner Dr. Johnston had the faculty of imparting confidence to an unusual degree. He had a calm manner, a quiet but firm voice and a gentleness and tenderness which soon made him beloved by his patients. A careful diagnostician, sparing no pains to ferret out the details of an obscure case, he was, in addition, a skilful therapeutist, not believing in many drugs (as was natural in a student of Hughes Bennett), but displaying a full mastery over the important ones. The demands of teaching and of a most exacting practice were met with unflagging energy, and throughout the past winter he was able to accomplish an extraordinary amount of work. About two weeks before his death he had an attack of severe substernal pain, with great prostration. He recovered sufficiently to go to Atlantic City, where he had a second severe attack, in the convalescence from which he died suddenly.

Dr. Johnston will be missed by a large circle of friends in the profession, particularly at the Washington meetings of the special societies and of the Congress, in the arrangements for which he always took an active interest.

We are glad to learn that he leaves a son in the profession, Dr. W. B. Johnston (at present one of the assistants of Professor Osler), in whom we hope the profession may find a worthy successor to his father and grandfather.

CORRESPONDENCE.

OUR LONDON LETTER.

(From Our Special Correspondent.)

London, March 8, 1902.

THE SMALLPOX EPIDEMIC; WILL IT SPOIL THE CORONATION PAGEANT? THE JENNER FAMILY.

The visitation of smallpox which began last summer is slowly but steadily gaining ground in London. The epidemiologists tell us that a considerable outbreak is now due. The disease, where not prevented, as in Germany, by efficient vaccination, shows a prevalence curve which attains its height every thirty-three years or thereabouts. Our last visitation was in 1871. This one has again found us ill-prepared; the Antivaccination League has pursued its mischievous propaganda all over the country and the medical profession, secure in its own belief, has not taken the trouble to carry on a counter-campaign. The Royal Commission on Vac-

cination which reported some half a dozen years ago recommended that compulsory vaccination should be abolished; in doing so it only formally recognized the fact that, although vaccination was *de jure* compulsory, it was not in many parts of the country *de facto* "compelled." John Bull, as was said by some one who knew him well, dearly prizes the privilege of going to the devil in his own way, and accordingly he resented the idea of compulsion. When defaulters were dealt with by the legal authorities, they were treated by their brother fanatics as martyrs to the blessed truth that vaccination is an unclean thing; their fines were paid for them, and when they came out of prison they were met by a rabble of sympathizers with bands and banners. The new Act stopped all this, but it created a strange being called the "conscientious objector" who is suffered to allow his offspring to go unvaccinated if he gets a certificate of exemption from a magistrate. This ceremony involves a trifling amount of trouble as the applicant has to appear in person and has besides to pay a shilling for the document. These conditions, though they can scarcely be called onerous, have proved sufficient to damp a good deal of cheap enthusiasm, and there has been a marked increase in the amount of vaccination in the last two years. London, however, is still very imperfectly protected, and in the parish of St. Pancras where the present epidemic broke out it is estimated that about a third of the rising generation had escaped what Dr. Job Collins, a member of the London County Council and one of our antivaccination heresiarchs, calls the "Jennerian rite." The health authorities have displayed great energy in persuading people to submit to the "rite," and for many weeks every other person one met in the street wore a red band on his left arm as a warning to the casual passerby not to rub against him. There has, however, been a good deal of carelessness in other matters. A week or two ago the attention of the President of the Local Government Board was called in Parliament to the fact that a patient in one of the hospital ships for smallpox cases had been visited by his mother and sister, the former of whom was shortly afterward herself admitted as a patient. The President stated in reply that every precaution was taken by the officials of the Metropolitan Asylums Board under whose control the hospital ships are to minimize the risk of infection being spread by persons visiting patients. He said the visitors on their arrival are invited to partake of a light meal in order that they may be physically better able to resist infection. They are then seen by a medical officer, who inquires into their condition as to vaccination, and, if necessary, urges on them the advisability of immediate revaccination. Before entering the wards the visitors are dressed in overalls and caps, and while in the wards they are on no account allowed to touch or in any way handle their relatives or the beds on which patients are lying. After a brief stay in the wards—some minutes only—the visitors are taken to a dressing-room where the overalls and caps are removed, and they themselves undergo a thorough washing of the hands and face before leaving the hospital premises. The fact of every visit is communicated by letter to the medical officer of health in whose district the visitor resides, whether that visitor has been recently revaccinated or otherwise. In the case referred to in the question the two visitors refused to be revaccinated at the time of their visit to the ships. Notwithstanding this official statement it is whispered that the authorities of the smallpox hospitals have been extraordinarily lax in admitting visitors. I am informed that at least seventy persons who have been allowed to visit friends in the hospitals have returned as patients during the last two or three months. This laxity is all the more remarkable as the general hospitals have been very strict in forbidding the admission of visitors.

The epidemiologists say that the epidemic will not reach its highest point till May and June. This raises an interesting question as to the Coronation of King Edward the Seventh which is fixed for the end of June. The pageant is certain to attract enormous crowds of people who will be packed in dense masses in the streets and windows, perhaps even on the chimney tops to which, according to Mark Antony, the Roman people climbed "to see great Cæsar pass." We hear that a trifle of 20,000 Americans are expected to grace the festival. But there is an ominous rumor abroad that it is quite possible that there will be no processions at all in connection with the Coronation. The King is said to be unwilling to be the cause of possible danger to his lieges by gathering together a vast concourse of people when the germs of smallpox are borne about in countless numbers "horsed on the sightless couriers of the air." The Coronation will not, however, be put off, and it is difficult to see how the King is to get to Westminster Abbey where the ceremony of making him "the Lord's Anointed" is to be carried out—unless he goes there in a cab in disguise.

In connection with vaccination it may be mentioned that Mr. Victor Plarr, Librarian of the Royal College of Surgeons of England, has recently unearthed some information as to the fate of the descendants of Edward Jenner, the discoverer of vaccination. He himself died wealthy, and his son Colonel Jenner inherited his wealth. But his nephews were less fortunate, for in 1840 a petition was presented to the House of Commons on behalf of Henry Jenner, Doctor of Medicine, and the Reverend George Charles Jenner, Clerk in Holy Orders, setting forth that the petitioners were the nephews of Dr. Edward Jenner; that they were of the respective ages of seventy-three and seventy-one years; that they both very materially assisted Doctor Edward Jenner in the investigation and practice of vaccination; and they expended nearly the whole of their property in promoting the object of Doctor Jenner's discovery; that Doctor Jenner would have been a much richer man if he had kept vaccination secret, and not divulged the practice of it for the benefit of mankind; that Doctor Jenner, by his will left Dr. Henry Jenner only an annuity of twenty-six guineas, and the Reverend George Charles Jenner a legacy of twenty pounds; "that under these circumstances your Petitioners humbly submit to the consideration of your honorable House their case, trusting that their services and for the sake of the memory of a man who conferred the greatest benefit upon the human race, that under Divine Providence was ever conferred upon it will not be passed over." Of the two nephews Jenner seems to have preferred George, the clergyman, who had in the first instance been educated for the medical profession. He and his brother Henry went as apostles of vaccination to Ireland. Things did not go well with Henry, for in 1839 he wrote, "I have sacrificed my health in and a vast deal of my time with anxiety, attention and exertion in the cause of vaccination, with much of my pecuniary resources and lessening my professional practice, indeed to such a degree as to induce my receding to a more humble station in society." Nothing seems to have come of the appeal to the generosity of Parliament. Henry died in 1851, at the age of eighty-four, at Berkley, where his famous uncle had practised; the date of his brother's death is unknown. In 1843 a son of his, Doctor William Henry Jenner, applied for the post of Inspector of Vaccinators at the National Vaccine Institution, but it was given to another. William

Henry died in 1850 and in 1860 his widow was for the third time a candidate for a pension from the Royal Medical Benevolent Fund. One hopes that she was successful; it is hardly conceivable how such claims as hers can have been passed over.

OUR BERLIN LETTER.

Berlin, March 15, 1902.

ETIOLOGY OF CANCER—SCHÜLLER AND HIS NEW PARASITE OF SYPHILIS—HEALTH OF DR. VIRCHOW—DEATH OF PROF. WOLFF—BISMARCK'S PHYSICIAN IN WARFARE.

The question of the etiology of cancer is at present a very burning one, as the newest statistics prove a decided increase of the malady for all civilized countries. In England, for instance, of one million inhabitants in the decades 1861-70, 3,840, in 1871-80, 4,680, and in 1881-90, 5,890 people died from this disease. In the Netherlands in 1874, there were 490 deaths, and in 1897, 910 deaths from cancer for each million of inhabitants. For Switzerland the ratio is 1,324, and in New York the number of cancer deaths in 1888 was 2,473, in 1897 4,117.

Your readers probably remember that it was claimed by Prof. Czerny of Heidelberg that the parasites of Schüller were in reality cork cells, to which statements the latter replied in the "Deutsche medicinische Wochenschrift" (No. 36, 1901), that the conclusion of Czerny was entirely erroneous, as he, Schüller, had his culture tubes closed exclusively with rubber or glass stoppers and that all fluids used by him had been previously filtered. True, the capsules which contained the parasites had some resemblance to cork cells, but this he had mentioned already in his book. However, he has told your correspondent that since this utterance from Heidelberg he had taken special precautions to avoid the use of cork and could nevertheless find the same organisms in all his examinations, sometimes capsules filled with young parasites, sometimes empty capsules, and again non-encapsulated parasites. Rost, a pupil of Koch, has propagated the same parasite for the first time. Schüller himself observed contractile movements of the live organisms, as well as their typical reaction against heat and alcohol, and he said he could follow all phases of development of the young organisms in trial animals injected with his cultures. Schüller desired very much the help of the Government to facilitate his researches, inasmuch as he, though an eminent surgeon, is not rich; but he is not favored by the powers that be and he must "paddle his own canoe" and also defend himself against the skepticisms of his confrères. He has also discovered a parasite of syphilis, of which your correspondent has seen some specimens. He will soon publish his new discovery, which he claims can be demonstrated not alone in primary infections, but in luetic cases of long standing and in hereditary syphilis.

The health of Prof. R. Virchow is physically all that could be expected after such a painful accident in a man of his age; mentally, he is not the same, it is said. His memory is defective and it is very doubtful if he will ever be able to resume his old position at the University.

In the death of Prof. J. Wolff, popularly called "the Bone Wolff," the Berlin University has lost a very good man. It was his individual work to prove that the arrangement in the formation of the bones represents the static laws. He also was the first to close the defects of harelip and cleft palate. He died of cerebral thrombus, after an illness of only two days.

A stage of open war, which is rather unique, exists between the physicians attached formerly to the County Hospital at Gross Lichterfelde, a suburb of Berlin, and the managing physician, Prof. Schweninger, formerly the court physician of Prince Otto von Bismarck. He seems to have some peculiar notions in regard to medical affairs, which are not relished by the other physicians. For instance, he does not believe in the value of statistics, does not permit the use of diphtheria serum in diphtheria cases, looks extremely doubtful at the operation of tracheotomy and does not favor the practice of surgery in general. The institute is presently without a surgeon, the former incumbent was Prof. Schleich, of anesthesia fame. Thus far the Government has upheld Prof. Schweninger, but the county representatives refuse to contribute any money until the affair is settled.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 6, 1902.

The President, Robert F. Weir, M.D., in the Chair.

The scientific business of the evening consisted of a meeting of the Surgical Section before the Academy. The use of the X-rays in the treatment of malignant disease was the subject discussed. The paper of the evening was read by Dr. Francis H. Williams of Boston.

X-Rays in Medicine.—Dr. Williams said that in discussing the question of the therapeutic effect of the X-rays one must not lose sight of the place that Roentgen's discovery has already made for itself in the domain of medicine. In certain branches of diagnosis, the X-rays now represent one of the most conclusive and most useful methods of obtaining accurate information. Without them the diagnosis of fractures would lose not a little of its present-day certainty. In thoracic disease data have been given for the accurate recognition of degenerative lesions. In tuberculosis, in aneurism, in the matter of intrathoracic growths and, generally, in the usually obscure diagnostic field of thoracic work, the X-rays have proved a veritable touchstone for the eliciting of truth.

Technic of X-Rays.—With regard to the therapeutic effects of X-rays the question of the method of producing the rays is of the first importance. It used to be said that the X-rays as obtained from a static machine were not effective therapeutically, and that it was necessary for remedial action to produce them by means of a Ruhmkorff coil. Further observation has shown, however, that X-rays obtained through either source are of about equal therapeutic value in their effect if other conditions are properly arranged. Dr. Williams uses a static machine for the production of the X-rays in hospital work, and a coil at his office. The static machine consists of eight plates six feet in diameter. Much more important than the source of the electrical energy is the matter of choice of the tube to be employed. In low-resistance tubes many of the rays are absorbed but they are not in the high resistance tubes. These latter should be used for tumors situated deeply in the tissues and the former for superficial growths.

Application to Patient.—A perforated diaphragm of lead should be so used that the rays produce their effect upon the tissues only a little beyond the diseased area. Pure tin is more agreeable and easier to handle than lead and is often employed for this purpose. As the seance must continue at times for as long as twenty minutes, the first care should be that the patient shall be in a comfortable position. Dr. Williams has found it important to enclose the tube within a box in order to protect the operator and others who may be in close proximity, as well as other parts of the patient himself, from the effect of the rays. If the inside of the box be

well coated with white lead it will very well serve its purpose of preventing the action of the rays.

Length of Exposure.—At first the exposure of the part to the rays should not extend beyond five, or at most ten minutes, so as to enable the operator to recognize how much effect is being produced and to forestall any possible idiosyncrasy as regards oversensitiveness of the patient to the rays. The exposure should be made two or three times a week. In tumors that are of slow growth very little result will be noticed from such short exposures, and they will have to be submitted to the rays for twenty minutes or even longer; in rapidly-growing tumors an exposure of five minutes may prove too long. The operator must be careful that the X-rays do not act as a stimulant as the knife does in some cases of rapidly-growing tumors, causing an efflorescence of malignant energy. The first sensation from the application of the rays is usually a sense of itching, prickling or a drawing feeling in the skin. This may usually be considered a favorable sign. In epithelial growths it must be remembered that the effect of the rays is to cause a breaking-down of the malignant tissue overgrowth, though healthy tissues in the neighborhood should not be affected.

Treatment of Rodent Ulcer.—Rodent ulcers are much slower to react to the action of the X-rays than is almost any other form of malignant growth, though the ultimate results are not unfavorable. As a rule, this form of growth is also more obstinate to treatment. As healing of the edges of the ulcer occurs, the opening in the tin or lead diaphragm should be made smaller so as to prevent the action of the rays upon the recently-healed tissues. In this way the ulcer can gradually be brought to complete healing. When glands are affected, these should also be exposed to the action of the rays, and, in general, the X-rays should be directed over the parts to which the lymphatic canals of the tissues lead.

Possibilities of Injury.—It has sometimes been the custom to allow a non-medical man to apply the X-rays. As a rule, such men are only mechanics who understand the production of the X-rays, but nothing about their therapeutic effects. Only imperfect success may be looked for under such circumstances and there are many possibilities of harm being done. Rawlins showed that guinea-pigs may be killed by frequent exposure to the X-rays, even though no external lesion becomes visible. Control guinea-pigs, kept for some time under the same circumstances as the others, but without exposure to the X-rays, were living and well when their companions died. Notwithstanding this, there is little danger of serious results in careful application. The experience of the Boston City Hospital, where thousands of exposures have been made without a single burn, suffices to prove this.

Results of Treatment.—In most of the cases of malignant growth treated by Dr. Williams, microscopical examinations confirmed the clinical diagnosis. So far no malignant superficial growth has failed to yield to the X-rays. This same favorable result has been obtained also in a chronic inflammatory lesion, wrongly suspected of being an epithelioma, and even in a localized nodule of tuberculosis. Rapidly-growing malignant neoplasms are very quickly affected. Slowly-growing neoplasms take longer to be affected. The site of the growth is the most important consideration for prognosis. Epitheliomata upon the face, upon the hand, upon the breast, and upon the tongue have been cured. Thus far every malignant growth, even though not ultimately cured, has been benefited by the treatment. The earlier the cases come for treatment the better is the prognosis.

Inoperable Advanced Cases.—In these cases the patients can always be promised great relief from the painful symptoms. Dr. Williams has had a case of rodent ulcer that had been operated upon five times, until finally operation became impracticable. Exposures to the Roentgen rays then became a renewed source of hope and consolation, besides greatly adding to the material comfort of the patient. There can be no hesitation in using the Roentgen rays when these are the only hope. For milder cases, however, the conscientious medical man will sometimes hesitate as to whether the knife should not be used. Dr. Williams' own conclusion in the matter is that it takes but a very short time to demonstrate whether or not the Roentgen rays are liable to be of benefit. In two weeks at the most, especially in cases of epithelioma, it will be very plain if there is to be failure of therapeutic effect. Then the surgeon can be called without the delay having added anything to the seriousness of the case. There is no doubt that at times after operation, as a result of the irritation of the tissues and the stimulus of the reparative process that ensues, a malignant neoplasm is stirred into great activity. Hence the advisability of applying the Roentgen rays first in order to test their therapeutic effect, and the knife only later. This seems to be the part of true conservatism.

Illustrative Cases.—Dr. Williams exhibited stereoscopic pictures of various patients who had been benefited by treatment. In one case, that of an old woman, an epithelioma began to improve after the second treatment. In some cases epitheliomata cured by exposure to the Roentgen rays have remained healed for over a year with no signs of recurrence. In only one case in Dr. Williams' experience has there been a recurrence; in this the patient suffering from an epitheliomatous ulcer received a series of treatments, and then, owing to circumstances, and the occurrence of so much improvement that there was no longer any discomfort associated with the growth, nor any tendency to advance, he ceased taking the treatment. The ulcerative lesion continued its favorable progress and healed completely without further treatment. Some six months afterward, however, the cutaneous tissues again broke down and treatment was carefully kept up until the spot was entirely healed. Since then there has been no sign of recurrence. Some cases of carcinoma of the tongue have improved greatly as the result of exposure to the Roentgen rays, but there has been inevitable recurrence in all these cases. The tissues of the tongue are so succulent that the carcinomata seem to acquire a very firm hold. One reason for the failure was that the cases were, as a rule, far advanced when brought for treatment. For favorable prognosis of treatment with the Roentgen rays, an early stage is important. Now, however, that patients know that they may be treated without recourse to the knife, it is probable that many cases will come much earlier than before when fear of the knife was all that kept them from consulting a physician. The earlier cases of cancer of the breast come for treatment by the X-rays, the more hopeful is the prospect. The nodular form of carcinoma is more easy to affect favorably than scirrhous cancer. It is wonderful to note how the hard breast, firmly fixed to the chest-wall, softens and becomes movable as the result of a few exposures to the Roentgen rays. Carcinomatous nodules in the glands shrivel up and disappear under their influence. The nodules of recurrent carcinoma occurring in the cicatrices of operation for the removal of carcinomatous breasts are especially amenable to treatment by the X-rays. Many of these discouraging cases will undoubtedly be cured by early applications of the X-rays, and this addition to one's armamentarium will help out surgical procedures. Dr. Williams exhibited the picture of a boy, six years

of age, who suffered from spindle-celled sarcoma of the elbow. Amputation was done in the upper third, but it was not long before symptoms of recurrence occurred. Sarcomatous nodules appeared in the scar, but under the influence of the X-rays the cicatrix has lost its redness and prominence, and, instead of the hard ridge that formerly marked the scar, there is no induration to be felt except in the central nodule of the scar.

Unfavorable Cases.—Dr. Williams described certain cases in which the X-rays gave relief from symptoms, but failed to produce a cure. One of these was a cancer of the neck which had been removed by operation and had recurred. As the result of the breaking-down of malignant tissue there was a large ulcer in the cervical region. After exposure to the X-rays there were distinct external improvement, less swelling in the cervical region, and much less ulceration. The internal discomfort, however, continued and even became more marked. It is evident that the internal portion of the cancer continued to spread and invade important tissues within the neck. In another case, rather similar, the cancer grew just below the ear; this too, after recurrence, was considerably improved by the X-rays, but difficulty of swallowing set in and continued to increase in spite of the X-ray treatment. It is only a question of time until these patients reach the fatal termination of their malignant disease. In these inoperable and hopeless cases, the feature of the X-ray treatment is relief of pain. Sometimes pain is so severe that even large amounts of morphine fail to relieve it. The first effect of the X-rays is a sense of comfort, which lasts, as a rule, for twenty-four hours, and enables the patient to sleep and even to eat much more heartily than would otherwise be the case. In recurrent carcinomata, even when there is not the slightest hope of ultimate cure by the X-rays, because of internal metastases, their therapeutic effect in producing relief from pain must be tried. Suggestion, of course, has something to do with the relief of pain in these cases, because the formidable apparatus employed has its due effect upon the minds of patients. There is no doubt, however, that relief of pain may be secured in individuals who are ordinarily unaffected by suggestion. Relief occurs even in patients who know nothing of the fact that the most promising part of the X-ray treatment is its amelioration of pain.

Hodgkins' Disease.—Dr. Williams exhibited a picture of a patient suffering from Hodgkins' disease, in whom there was a very marked difference in the size of the cervical regions on the two sides. Before the employment of the X-rays the cervical glands had been about equally affected, and now there is a very striking difference. All of the glands on one side of the body were exposed to the rays and all decreased: those on the other side were not exposed and remained absolutely unchanged. There was also a decrease in the size of the spleen as the result of the employment of X-rays.

Conclusions.—Dr. Williams said, in conclusion, that X-rays undoubtedly do good in cancer. Besides, they arouse no dread, hence patients will come for much earlier treatment than otherwise. There is no shock from their use, their employment is absolutely painless and the cosmetic results are better than from any other method of treatment. With regard to recurrence, one cannot as yet be sure. The X-rays, however, in this regard, certainly promise very well, and if there should be signs of recurrence one can promptly resume the treatment. With regard to internal cancers, the medical man is not justified in promising relief by the use of the X-rays; their employment may lessen discomfort, however, and all external cancers yield absolutely to them. Inoperable cancers will become much more rare, because in very early stages malignant growths will be submitted to the X-rays.

Quality of X-Rays.—In discussing Dr. Williams' paper, Dr. William J. Morton said that there are two forms of X-ray tubes, those of low and those of high vacuum. High-vacuum tubes give a lack of definition in radiographs that indicates their diffusion through the tissues and a certain absorption of the energy. This is undoubtedly the best form of tube to use for therapeutic purposes. The low-vacuum tubes that give the best radiographs are not so effective. Dr. Morton said that his experience justifies him in believing that the X-rays are sure to be of service in many forms of cancer. Dr. Morton's clinical experiences will be found in the report of the Harvard Medical Society proceedings, soon to be published in the Medical News.

Relief in Inoperable Cases.—Dr. A. B. Johnson said that he has had some encouraging results with the X-rays, especially in the recurrence of cancer after operation upon the female breast. This favorable experience also extends to a case of recurrence of carcinoma of the jaw with ulceration into the mouth. He believes that the tubes of large potential electrical energies should be employed and that they should be artificially cooled by means of a water reservoir. He detailed these cases and showed the extremely favorable results, though as yet no absolute cure has been obtained. In one case in which there was a very deep ulcer, the edges of which bled very easily, after two exposures the tendency to bleeding ceased entirely; after four exposures, healthy granulation tissue began to fill up the ulcerated space and it healed like a healthy granulating ulcer. As a rule, in his experience, relief from pain is a very marked feature. The night after an exposure to the X-rays, patients, who had previously been very uncomfortable, rest very quietly. Undoubtedly, with larger apparatus, the X-ray operator will be able to treat carcinomata in deeper tissues than at present.

Unsatisfactory for Rapidly-Growing Tumors.—Dr. William B. Coley reported a series of six cases of sarcoma on which the X-rays had been used at the General Memorial Hospital. One case was that of a rapidly-growing tumor of the right parotid region; it proved to be of extremely malignant character and recurred very shortly after operation. Dr. Coley then tied the external carotid artery and employed the mixed toxins for its treatment. Neither the ligation of the artery nor injection of the toxins had the slightest effect in preventing the growth of the tumor. Eight treatments with the X-rays also produced no effect. The second case was a rapidly-growing sarcoma of the upper jaw. This involved so much tissue when seen that surgical procedures seemed out of the question and the toxins were used without effect. The tumor was then exposed to the X-rays on eleven successive days, but without any improvement. In another case of carcinoma eight treatments with the X-rays had but very slight effect in limiting the growth of the tumor at first, and then ceased entirely to produce any effect.

Slower Sarcomata.—In one case of not very rapidly-growing sarcoma of the femur the tumor has been reduced somewhat in size and the patient is more comfortable. In case of inoperable tumor of the neck which was treated by the mixed toxins, but subsequently recurred, great improvement resulted from the use of X-rays. Not only was the patient made more comfortable, but the tumor was reduced in size and there is even the promise of an ultimate good result. In another patient, operated upon sixteen years ago at the New York Hospital, the tumor was found on pathological examination to be of the round-cell variety. Three

operations were done during the next three years. The first tumor did not seem to have any capsule; later tumors were capsulated. A tumor the size of the first finally developed, was treated with the X-rays and has practically entirely healed.

Epithelioma after Lupus.—Dr. Charles W. Allen presented a patient who, after having suffered from lupus for twenty-four years, developed an epithelio-matous nodule in the midst of a lupus scar. This was treated by means of the X-rays and has improved so much that an ultimate cure seems assured. Dr. Allen, contrary to the experience of Dr. Williams, has found that a rodent ulcer yields without much difficulty to the X-rays. In a recent case, in which a cancerous mass pushed itself out from the surface of the cheek in front of the globe of the eye, after one exposure the mass began to slough away, while its base softened and shriveled up. The pain after the application of the X-ray was cured without suggestion.

Long-standing Carcinoma and Erythematous Lupus.—Dr. Percy Turnure presented a patient who suffered from an injury of the cheek thirty-five years ago which had never completely healed. Six or seven years ago malignant degeneration of the ulcer set in, and about five years ago it began to involve the eyeball; the glands of the neck became involved and the cancer seemed inoperable. The use of the X-rays has produced a profuse discharge and has added greatly to the comfort of the patient. The case, however, seems almost too far gone to present a favorable prospect of cure. Glands that are affected by malignant processes seem to disappear rather easily under the use of the X-rays. Dr. Turnure has come to the conclusion that most of these glands are enlarged not really because of cancerous degeneration, but because of the suppurative process that goes on in breaking down malignant growths. Dr. Turnure has recently had a case of erythematous lupus of very long standing which has been greatly benefited by the X-rays. The patient was exhibited and showed a distinct difference between the parts that have undergone exposure to the X-rays and those which have been left unexposed.

Recurrent Carcinomatous Nodules.—Dr. Hopkins of Brooklyn said that it is in recurrences of cancer after operation that the X-rays are especially valuable. He has recently had under observation a case in which seven nodules, some of them ulcerating, occurred in the scar after operation for removal of the breast. Five of these have already disappeared as the result of exposure to the X-rays and others are disappearing. This improvement in the pathological condition has taken place notwithstanding the fact that the patient is pregnant, and the pregnancy has not been interrupted. It is surely a wonderful power for good that can prevent the stimulus of pregnancy from influencing unfavorably a malignant tumor in the breast. In another case under Dr. Hopkins' care a sausage-like scar, evidently due to cancerous recurrence after amputation of the breast, is rapidly disappearing. A malignant tumor of the tongue that had increased the size of the organ to such an extent as to prevent absolutely the taking of all nourishment, so that the patient had to be nourished by the rectum, was caused to ulcerate by exposure to the X-rays, and the tumor has decreased so much that, whereas a teaspoonful of water could not be taken before, the patient is now able to eat steak and other nutritious substances, has gained in weight and has taken on a sense of well-being that had been absent for a long time.

Lessened Chance of Burns.—Dr. Williams, in closing the discussion, said that, in his experience, when the screen is employed there is much less chance of burning the patient. It is possible to produce a brush burn with electricity when the X-rays are not employed at all. Dr. Williams confesses that patients are not absolutely protected from all danger of burns even by the screen, though there is undoubtedly much less risk. As burns are the one serious drawback to the use of the X-rays, it is worth while to take the precautions thus suggested. In using the X-rays in cavities of the body, Dr. Williams believes that they should be employed through funnels of glass, instruments easily used and absolutely shutting off the rays from all points that it is not desired to affect. This protection for the healthy tissues, especially the healthy mucous membrane, is very important and should not be neglected. The danger at the present moment is that, in the enthusiastic use of the X-rays by unskilled operators, serious damage will be done, bringing this method of treatment into uncalled for disrepute. Insistence on precautions that seem demanded by the experience of operators who have extensively used this method of treatment is an extremely important matter. No harm can possibly result, the patient will be better protected, no true therapeutic effect of the X-rays is diminished and a proper sense of security in their employment is obtained.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

Stated Meeting, Held January 17, 1902.

George R. Elliott, M.D., Chairman.

Webbed Fingers.—Dr. W. R. Townsend presented a baby four months old, showing a mild type of webbed fingers. The webbed hand was the smaller, the fore and middle fingers showing the web; no other congenital deformities were present. No explanation was offered to account for the extreme smallness of the webbed hand.

Hemihypertrophy of the Bones of the Face and Head.—Dr. Townsend also presented the case of a girl four years old. The right side of the face and head seemed larger. When first seen edematous tissue over the back of the head rendered it difficult to determine whether the bones were enlarged or not. The edema subsequently decreased and an increased size of the occipital and right parietal bones was manifest. The frontal bone was not involved, but the right inferior maxillary bone appeared enlarged. There was no history of syphilis; lower extremities were developed. The child had an enlarged abdomen and the deformity known as chicken-breast. The exact diagnosis was puzzling, the question being whether it was leontiasis or rachitis.

Aspiration Treatment of Abscesses.—A boy, eight years old, was also presented by Dr. Townsend, who, January 9, 1901, gave the history of hip disease of one year's duration. There was an abscess on the outer aspect of the thigh which was aspirated April 6th; it refilled, was again aspirated on April 29th and again on May 11th. The abscess did not recur. The case was presented to illustrate the successful treatment of these abscesses by aspiration. He said abscesses not interfering with application of braces, those not burrowing, and those not in a condition of mixed infection could be safely let alone or aspirated.

Dr. Nathan, in discussing the case of hemihypertrophy, stated that after careful study of the literature of reported cases of leontiasis ossea, it did not appear that there was any agreement between authorities as to the definite lesions constituting this condition. All the reported cases differed from one another and the one presented differed in many respects from all cases noted in the literature of the subject. He said that originally

in the case presented there was a distinct cleft in the occipital bone. There was certainly some enlargement of the occipital bone as determined by measurements, but the hypertrophy of the soft parts over the lower maxilla made it difficult to measure that bone.

Dr. V. P. Gibney, in discussing the case of abscess treated by aspiration, presented statistics from his private records of twenty-three cases treated by aspiration, fifteen of which were cured. Of these fifteen, in three cases the aspiration was done once; in four cases, twice; in four cases, three times; in four cases, four or more times. Of the remaining eight, three were aspirated once, but the needle was large and caused leakage and sinus formation; four were aspirated twice; in one spontaneous opening took place a few days later. In all cases not cured there was no damage done by the aspiration.

Dr. T. Halsted Myers expressed himself as in favor of non-operative treatment when the tuberculous abscesses were not infected and were not interfering with the patient's health or threatening another joint. He had seen many cases cured without operative interference and considered this best in dispensary practice; aspiration should be tried before more radical operative measures.

Dr. R. H. Sayre said that he had aspirated frequently and sometimes secured good results, sometimes not. He had seen many cases get well without treatment and cited one case of recurrent abscess of the thigh; if these abscesses could not be opened and kept surgically clean, he advised aspiration, or, if this were not practicable, that they be let alone.

Dr. George R. Elliott asked Dr. Gibney if his statistics included any spinal abscesses.

Dr. Gibney replied that they referred to abscesses connected with the hip only. He further stated that he had had cases of spontaneous disappearance, but that most of the psoas abscesses had been of long duration that had been given up under the expectant plan of treatment.

Torticollis.—Dr. Royal Whitman presented the case of a boy twelve years of age, illustrating treatment of severe torticollis by the open incision with overcorrection of the deformity. The operation was performed November 7, 1901, and resulted in correction of the deformity with no limitation of motion, all resistant structures were divided, the two insertions of the sternocleidomastoid muscle and the cervical fascia being the most important.

Dr. Myers said the operation should be done early. He had seen cases left until the individual was fifteen years old, in which the sternal ends of the clavicles had been partially dislocated upward by the short sternocleidomastoid; this was a deformity difficult to correct.

Congenital Anterior Displacement of the Hip.—Dr. Whitman presented a girl five years old, illustrating congenital anterior displacement of the hip. He said ordinary methods of replacement were not successful in such cases and whatever treatment was adopted must be supplemented by osteotomy of the femur, otherwise the head of the bone would be displaced when the parallelism of the limbs was restored.

Dr. Fiske said he thought the condition should be regarded as a superior displacement rather than anterior.

Dr. Whitman replied that he understood the term congenital anterior displacement of the hip to indicate that the head of the femur was directed forward, lying below and to the outer side of the anterior superior spine.

Dr. Whitman also presented a child aged three years. The non-cutting operation had been performed one year previously. The plaster bandage was worn only seven months. This illustrated the fact that in certain cases of a favorable type cure might be accomplished in a short time, cure meaning both as to function and position. It was impossible to say from observation which hip had been originally displaced.

Double Congenital Hip Dislocation Treated by the Open Method.—Dr. Whitman presented a patient, a girl seven years of age, upon whom he had operated by the open method three years previously. The patient now walks with but slight swaying of the body; the lordosis has completely disappeared, and the permanency of the cure is assured by the lapse of time; there is practically no restriction of normal motion.

Dr. Elliott asked if the two operations were performed at the same time and if much acetabular scooping had been done.

Dr. Whitman replied that the operations were performed about three weeks apart; the heads of the bones in this case were easily replaced and very little scooping was necessary; he considered one advantage of the scooping that it caused adhesions which bound the bones more firmly and prevented subsequent displacement; the amount of scooping differed in different cases, some requiring a great deal, while in others simple arthrotomy might be sufficient. He further stated that after operations of this character the fixation bandage should be employed for many months, exercise and passive motion being useless until complete repair had taken place. In one instance he had fixed the limb for eight months and at the end of that time the motion was far less restricted than in the majority of cases in which the restraint had been removed soon after the operation.

Phocomelia.—Dr. Henry Ling Taylor presented the case of a girl five and one-half years old, the second of four children; no developmental anomalies in the family. The mother stated that the feet presented, and that something was wrong with the shoulder at birth, which was rectified by the physician. When the child began to walk at fourteen months, a slight lameness on the left side was noticed which has persisted. Motion at the hip was normal, but the left leg was two inches shorter than the right, the shortening being confined to the femur; the trochanters were in normal position and the classical signs of congenital dislocation and coxa vara were absent. He offered the diagnosis of congenital shortening of the left femur, confirmed by a skiagraph which showed the femur to be short and small. The points of interest were the differential diagnosis, the slight lameness with considerable shortening, which was the rule when the joint motion and muscular power were good, and the absence of true lateral curvature with a markedly sloping pelvis, which was also the rule.

Dr. Elliott asked Dr. Taylor for the etymology of the word phocomelia. Dr. Taylor replied that it was derived from two Greek words meaning seal and limb, the combination being equivalent to flipper deformity. The term had reference to imperfect development in length of one or more of the long bones of the extremities.

Dr. Sayre considered that the term phocomelia should be restricted to the extreme cases in which the long bones were either absent or almost entirely so, but Dr. Taylor responded that Kummel, Klaussner and other authorities applied the term to such cases as the one presented.

Dr Alfred Taylor presented a case of webb fingers. The patient was operated on recently, but some of the fingers were in a condition to show the results of the operation. The patient, a boy, was born with three fingers of each hand entirely webbed to the tips. On the middle and ring fingers of both hands the bases of the

terminal phalanges had grown together, the little finger showed no bony union. The first operation was done in November on the little finger of the left hand. Later the entire condition of the right hand was relieved by operation. The method was to make an incision on the dorsum of one finger and palmar surface of the other, dissect up the flaps, using the opposite flaps to cover the fingers. In the little finger primary union was obtained. Instead of making a crosscut at the base of the flap or instead of making a V-shaped flap, the incision was simply carried to the full distance up toward the web in each case, when it was found that by suturing the edges together the edge of one flap would obliquely cross the edge of the other in an opposite direction, the two edges meeting in the middle. This method worked very well.

"The Operative Treatment of Webbed Fingers with Presentation of Cases."—This was the title of a paper read by Dr. Sayre. He reviewed briefly the classical methods of operation and illustrated on a model his method of operation, by making a flap for one finger and grafting to cover the other, then taking an A-shaped flap from the dorsum of the hand, slipping it over and stitching it to the palm to form the bottom of the web. In methods which did not employ a graft from some other part of the body to cover the inner side of one finger, the effort was made to cover a defect with insufficient material, since the web connecting two contiguous fingers was much less extensive than the amount of skin which would cover the contiguous margins of those fingers normally and pass into the interdigital cleft. For demonstration a stuffed glove of one color was slipped inside one of a different color, the fingers of the latter being sewed together to present webbing after the removal of the piece of kid lying on the contiguous sides of the webbed fingers.

Dr. Myers considered grafting a great improvement over the other methods in these cases. Only the bottom of the cleft need be covered by a flap.

Dr. V. P. Gibney stated that he had always used the Didot method of operation, but thought Dr. Sayre's plan an excellent one.

Dr. Sayre presented a patient upon whom he had operated for webbed fingers. The fingers were webbed to the tips and the phalanges united by bony union. The case illustrated the method of making a flap for one finger and using skin graft for the other.

BOOK REVIEWS.

Practical Medicine Series of Year-Books. General Surgery. Edited by Dr. John B. Murphy. The Year-Book Publishers, Chicago.

In the admirable library comprised in the "Practical Medicine Series of Year-Books," the volume on Surgery for the past twelve months was assigned to Prof. Murphy of Chicago. The name of the editor is a sufficient guarantee of the practical value of the book, which is written from the standpoint of the clinician and of the operative surgeon rather than from that of the pathologist or of the student.

Every branch of the subject, from anesthetics to military surgery, is discussed in such a way that the reader arrives at a very fair idea of the most notable advances that have been made, and also of the critical attitude of the rest of the profession toward the theories that have recently been advanced. The various topics, including such matters as spinal anesthesia, the etiology of tumors, the new methods of diagnosis in kidney diseases, and so forth, are treated with marked fairness and impartiality. The only fault which one could find with the volume is that it takes comparatively too little note of foreign contributions, although the American journals are very well sifted and analyzed.

Lamarck. The Founder of Evolution. His Life and Work. With Translations of his Writings on Organic Evolution. By Alpheus S. Packard, M.D., LL.D. Longmans, Green and Co., New York, London and Bombay.

It is not a rare occurrence in this hurly-burly world that the germs of fruitful and even epoch-making ideas are lost for many a year to break forth into life and vigor. At the present time when Neo-Lamarckism and Neo-Darwinism are set forth as rival claimants to the position of the true light of interpretation for evolution it is a pleasure to have a work of this kind and to learn more of the life of a man whose great ideas were lost in the light of Darwin's intellect.

Dr. Packard, whose work with insects has endeared him to every student of this branch of science, has given us a labor of love in this excellent biography. In his own inimitable style he has made Lamarck a living personality and he has moreover set before the science-loving world a clearer picture of the fundamentals of organic evolution than has been vouchsafed for many a year.

We recommend this volume most cordially to all those who enjoy the story of the lives of those who have made science.

The Principles of Pathological Histology. By Harvey R. Gaylord, M.D., Professor of Surgical Pathology in the University of Buffalo, and Ludwig Aschoff, M.D., Professor and First Assistant in the Pathological Institute of Göttingen. With an Introductory Note by William H. Welch, M.D. Lea Brothers & Co., New York and Philadelphia.

For beauty of illustration and marked originality in conception this work stands out in sharp contrast to other works along similar lines of study. The reviewer does not recall any work of just this character as having appeared in recent years at least. It has all the advantages of a collaboration with a coworker in Professor Orth's laboratory at Göttingen and is adapted to the use of American students at the same time.

Each year sees marked improvement in the text-books for students of medicine in the United States, and it may be asserted without fear of contradiction that the present work is one of the best results of the art of good book-making and withal an immensely valuable guide to the student of pathological histology.

The work is to be most cordially commended as complete, authoritative, and at the same time a work of art. The chapter on Photomicrography is especially commendable for its simplicity as well as for its thoroughness.

Studies in Physiological Chemistry. Being Reprints of the more Important Studies Issued from the Laboratory of Physiological Chemistry, Sheffield Scientific School of Yale University, during the years 1897-1900. Edited by R. H. Chittenden, Ph.D., Professor of Physiological Chemistry and Director of the Sheffield Scientific School. Charles Scribner's Sons, New York.

There is one feature of this work that impresses the reviewer above all others and which makes it even more important and pleasant to speak of the man than of the work. There is a great fertility of intellect, a driving energy and a great sympathetic interest, all made manifest in the records of Dr. Chittenden's work. In the opening pages a bibliography is appended of a large list of studies in which, one after another, the guiding and

stimulating interest of the teacher has trained the young student along lines of great usefulness.

Such men are needed in the medical schools of this country and it is a pleasure to note that there are to be found, now all over the country, many of them trained in this self-same laboratory of the work of which the present volume is but an index.

It is gratifying to the student trained in physiological chemistry to be able to have these collected essays of the last three years in a handy volume. We trust that many such volumes may be issued.

A System of Physiologic Therapeutics. Edited by Solomon Solis Cohen, A.M., M.D. Volume VI., Dietotherapy and Food in Health. By Nathan S. Davis, Jr., A.M., M.D. P. Blakiston's Son & Co., Philadelphia.

It is a cheerful sign of the times that the practising physician has made for his use text-books on practical subjects which closely follow the onward march of the more technical subjects. Such are, in the reviewers' parlance, termed "up to date." This work is of this class, and not yet wholly has the author been enabled to shake away from many of the traditional garments which have covered the dry bones of physiological chemistry.

When conflict seems to arise in the matter of food products and their values, between the chemist and the clinician, it behooves both to examine their ground more thoroughly, in order that the former may recognize the difference between test-tube reactions, strict physical chemics and the living chemistry of the body; and in order that the clinician may make haste slowly in jumping to conclusions as to the why and wherefore of good or bad results obtained.

The present work exemplifies in some measure an avoidance of both difficulties by calmly bolting both boluses and letting the reader work out his own salvation. Still, there is too little of this in any way to detract from the usefulness of the work. It is a very excellent one and is worthy of the highest commendation.

A Text-Book of Pharmacology and Some Allied Sciences (Therapeutics, Materia Medica, Pharmacy, Prescription-Writing, Toxicology, etc.). By Torald Sollmann, M.D., Assistant Professor of Pharmacology and Materia Medica in the Medical Department of the Western Reserve University, Cleveland, Ohio. W. B. Saunders and Co., Philadelphia and London.

It has rarely been our fortune to review so clear, concise and well-arranged a work as this treatise by Dr. Sollmann, which will, no doubt, quickly gain that confidence among students which it justly deserves. The pharmacist will find welcome information which other books on the same subject usually neglect and which nevertheless are essential for the broader conception of the subject.

The introductory chapters treat of pharmacognosy and the method of pharmacy and prescribing, then follow materia medica and therapeutics proper, while the last hundred pages consist of a chapter on practical exercises in chemistry and a very valuable one on the general technic of pharmacological research to which are appended several tables on solubility and dosage. Both the metric and the old system of weights are used and the British Pharmacopœia is considered, as well as our own. Short articles interspersed among the text upon the mechanism of the normal physiological processes greatly help to elucidate the action of the drugs and the tables comparing those of the same class with each other will prove of great value.

That the book is thoroughly up to date is proven by the consideration of such drugs as heroin, dionin, eucaine, hedonal, etc., and by articles on the subarachnoid injections of cocaine, and on internal secretions.

We regret to see that the dose of dionin has been omitted and that no mention has been made of the fluorides in the paragraph on preservation of food. Phloridzin among internal secretions is rather out of place and the toxicology could be a little more full, especially of such drugs as arsenic.

The article on anesthesia is good and worthy of a purely medical book; the same may be said of the very excellent table on antitoxins and protective serums. On the other hand, the chapter on specific infections is unnecessary in a book of this character, and, on account of its briefness, is scarcely instructive. There are about 100 illustrations, in the main schematic. We consider the book one of the best of its class and wish it every success.

The Perverts. By William Lee Howard, M.D. G. W. Dillingham, New York.

In novel form the author has most skilfully depicted the clinical history of a neurotic family. Sprung from the union of a worn-out man with partly "dried up New England school teacher," as the author puts it. Three daughters and one son, the hero, result from this marriage.

The chief interest centers in the son who has dipsomaniacal attacks. These are exceedingly well sketched and the author is to be congratulated on handling this difficult subject in so just and sensible a manner. His presentation has the fulness of truth in it. The hero is saved by his own study of the morbid process, as he is a physician, and he is helped by a sympathetic and noble woman whom he weds. One sister is a dominant figure in the story; she develops scientific tastes, enjoys animal experimentation, uses bacteria-infected whistles in trying to poison off her nephew and finally develops the erotic perversions of the flagellants.

The story is well told and offers an interesting study in morbid psychology.

BOOKS RECEIVED.

The Medical News *acknowledges the receipt of the following new publications. Reviews of those possessing special interest for the readers of the* Medical News *will shortly appear.*

Compend of General Pathology. By Dr. A. E. Thayer. 12mo., 321 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Handbook of Bacteriological Diagnosis for Practitioners. By Dr. W. D'Este Emery. 8vo., 216 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia.

Enzymes and their Applications. By Dr. J. Effront. Translated by S. C. Prescott, S. B. Vol. I., The Oxidases. 8vo., 320 pages. John Wiley & Sons, New York. $3.

Les Filatures de Lin. By Dr. D. Glibert. 8vo., 465 pages. Illustrated. Brussels.

The Pocket Gray or Anatomist's Vade-Mecum. By Dr. E. Cotterell. Fifth Edition, Revised and Edited. C. H. Fagge, 12mo., 270 pages. William Wood and Company, New York.

The American Year-Book of Medicine and Surgery. Edited by Dr. G. M. Gould. 2 vols. 8vo. W. B. Saunders & Company, Philadelphia and London.

Vier Vorlesungen aus der Allgemeinen Pathologie des Nervensystems. By Dr. F. W. Mott. 8vo., 112 pages. Illustrated. J. F. Bergmann, Wiesbaden; Stechert, New York.
